Today there exists much evidence of the role of sexual behavior as a determinant of sexually acquired disease and associated disability in the aged populations in developed countries. The recent emergence of STIs and HIV infection in older populations represents a measurable biological marker of at-risk sexual activity for a large proportion of aged individuals. Additional studies are needed to better explain the link between sexual activity in late ages and the risk of STI/HIV, also to enhance the effectiveness of preventive programs toward this growing population.

Counseling activities and screening programs for STIs and HIV infection must also be tailored for older persons, and their accessibility to STI clinics must be enhanced, particularly to reduce delays in diagnosis and improve the efficacy of treatments.

Today it is also clear that the risk of progressive enlargement of HIV epidemic is associated with unsafe sex by infected individuals

**Fig. 94.3:** Kaplan-Meier cumulative survival rate according to age group by age at seroconversion (Modified from Pezzotti et al. 1992).

and the fact that these individuals are older than the susceptible partner stresses the need to continuously improve preventative information, attitudes, and practices in this population.<sup>55</sup> Failure to consider HIV infection in older patients also contributes to the greater risk of older HIV-infected to present with an advanced disease at the diagnosis.

Moreover, the barriers to effective communication between older patients and physicians or other health caregivers about sexual behavior should be removed, to also better manage STI risk and occult HIV infection.

To date, no guidelines are available that specifically address the needs of an elderly STI/HIV-infected patient. Also for this reason, the pre-existing comorbidity and the increased susceptibility of older individuals to drug toxicity, stresses the need to improve their attitudes towards condom use and their perception of risks associated with sexual activity in order to prevent acquisition of any STI or HIV-1 infection.

### Summary

In recent decades, some factors have enhanced the sexual life of individuals in their sixties, seventies, and even eighties. Worldwide, this fact has growing the population of individuals in midlife and late adulthood who engage in sexual behaviour at-risk for HIV infection and other sexually transmitted infections (STI). In this chapter, selected studies are reviewed to disentangle the relationships among old age, sexuality, and infections. The different sections are focused from the biological and physiological changes observed in the sexual performances in old ages to the epidemiology and the clinical aspects of STI and HIV infection in elderly. Also some final suggestions are summarized to enhance the preventative pressure of the educational programmes targeted at this population.

# Sexually Transmitted Infections in the Female Sex Worker Community

Samarjit Jana • Geeta Sethi • D. Mandal

# 95

## Introduction

Our present understanding of 'sex work' includes male, female, and transgender sex workers. While the problems/issues in meeting the sexual health needs of all such workers hold equal importance, this chapter will deal only with female sex workers. However, most of the principles on which it is based are equally applicable to other groups of sex workers.

In the recent past, the issue of the management of sexually transmitted infections (STIs) among sex workers has assumed increasing importance because of the focus on HIV/AIDS prevention and care. There is a strong correlation between HIV and STI transmission. The presence of STIs in one partner facilitates both sexual transmission and acquisition of HIV. Preventive policies and principles including various tools that are applicable to STIs also hold good for HIV. HIV prevalence among the population of female sex workers in different cities across the world is found to be high.<sup>1</sup> STI prevalence rates in the Asia region continue to be high among sex workers. Studies conducted during 2000 in seven sites in India found seroprevalence of syphilis among sex workers to be ranging between 7% and 56%<sup>2</sup>; gonorrhea prevalence was found to be 36% among street-based sex workers in Dhaka, Bangladesh compared to only 0.5% among women attending health services.<sup>3-4</sup> Sex workers surveyed in 10 Indonesian cities during the year 2005 showed that 50% of them are infected with one or more curable STIs.<sup>5</sup> Comparable rates have been reported throughout the region, where HIV prevalence is consistently higher among sex workers—female, male, and transgender—than among other populations.<sup>6,7-11</sup> Yet, despite these high rates, only 20% of sex workers are currently estimated to have access to basic prevention services.<sup>12</sup>

Making good quality STI care and services available and accessible to sex workers could effectively slow down the transmission of HIV.

## Significance of STI Management in Sex Worker Communities

Even though the comparative size of the sex worker population in any given situation/country is small in relation to that of

the general population, special emphasis on the management of individual cases of STI as well as on the development of an effective STI management system is important because:

- Sex workers constitute the core group of transmitters of infection to the general population.
- Their work and social status places them at an increased risk of contracting infection from multiple partners.
- As sex work is an economic activity, the disease burden has a direct impact on their capacity to earn a livelihood and support themselves and their families.
- Effective STI prevention and care program has direct implications in the transmission of HIV/AIDS.

## Theoretical Construct

The classical medical model of disease management is based on a hypothesis that considers a linear relationship between the agent and the host. This model ignores all social and environmental factors that impinge upon the process of disease transmission, progression, and management. Although the limitations of this model are well-understood and documented in recent times, practices still remain unchanged. This is partly because the tremendous advances in the branch of curative medicine in the fifties and sixties dazzled the world and great emphasis and hope was thereby placed on disease control through individualized treatment and care, ignoring all other environmental and social factors.

Secondly, there are few well-accepted and articulated models of prevention and management that take account of social and environmental factors for diseases. The most effective approach is to view STI as an occupational disease and program planning should follow the basic policies and guidelines of workplace safety. This approach brings into focus all possible issues related to workplace environment, which directly or indirectly influence the health and well-being of workers engaged in the sex industry. This includes:

- Contractual agreements related to the work; involvement of other agencies such as law enforcing authorities, the municipal corporation, the department of social welfare, landlords, etc.; the recruitment of workers, stipulation of the minimum age, hours of

work and work conditions; a safe and secure work environment, and the provision of basic amenities, e.g., water and sanitation. In legalized brothels in Netherlands and Australia, brothel owners are compelled to follow the standard norms in providing safety and security and health services to individual sex workers in accordance with the laws and policies of the Government. Adequate compliance is assured through a system of supervision and monitoring and regular inspection.<sup>13</sup>

- The principles of the management of workplace safety followed in other settings usually emphasize the active participation of workers. The management and workers through state-mitigated policies and strategies jointly decide upon workplace safety standards and practices. Both workers and management are then obliged to follow them. Globally, experience shows that the participation of workers ensures an improvement in the quality of the safety of the workplace as well as that of the programs and services designed to improve health and safety. The experience in Sonagachi, Kolkata (India) and Tangail (Bangladesh) also demonstrates the effectiveness of sex workers' participation in ensuring workplace safety.<sup>14</sup>
- In occupational health programs, preventive and curative services are customarily integrated. This has special implications for the prevention of STIs especially among sex workers, as unless consistent condom use for prevention is ensured, the cycle of infection and reinfection cannot be broken.

## A Model for Comprehensive Management of STIs in Sex Workers

Planning and managing an effective STI service delivery program requires sufficient attention that to be paid not only to the biomedical and epidemiological aspects of disease transmission and progression, but also to important sociopolitical factors that influence outcome. Over the last decade, there has been considerable development in the areas of laboratory-based STI diagnoses and simplification of treatment modalities for many STIs. In the recent past, the use and application of point of care testing,<sup>15</sup> which provides immediate and accurate diagnoses, is getting importance. The single dose treatments for many STIs have improved the outcome of STI management. While there have been substantial developments in the biomedical field, and proven treatment regimens are well-established, the greater challenges still remain in developing effective and appropriate nonjudgmental services that adequately address the special conditions of marginal and stigmatized populations like female sex workers. Development of an effective and comprehensive STI management program among the sex workers calls for articulation of an appropriate strategy that needs to be based on community friendly guidelines and approaches.

### COMMUNITY LED STI MANAGEMENT APPROACHES

To improve both the quality and coverage of STI management services one needs to move beyond the traditional approaches to STI management – what restricts STI service development within

the four walls of the clinical medicine (e.g., doctor, medicine, and prescription). Social approaches to STI management have opened up new avenue to engage and involve service recipient as 'provider' and co-owner of service delivery system. Community led STI management approaches can be articulated under four 'D's' (destigmatization, demystification, deconstruction, and democratization).<sup>16</sup>

## Destigmatization of Sex, Sex Work, and Sexually Transmitted Infections

One of the primary reason behind improper and under utilization of STI services is linked to the shame and stigma attached to it. To begin with it can be addressed by the outreach and peer worker through introduction of human anatomy and physiology as part of health communication strategy. Sex workers should feel comfortable in observing and examining their own body including genital parts and develop a healthy and nonjudgmental attitude towards sex organ irrespective of her occupation. Outreach workers including peers should share with the community members appropriate knowledge and information about hygienic practices; in addition to that they should encourage sex workers to identify any painless ulcer in the genital part and report to attending doctors in the clinics which would help identifying nonsymptomatic cases including its timely intervention and treatment. This has immense importance in influencing the overall treatment seeking behavior of sex worker. All staff members of the program including peers and outreach worker must not view sex as a 'sinful act' and garner adequate confidence to discuss and deal with issues related to sex and sexually transmitted diseases (STDs).

## Demystification of the Technical Aspects of STD Services

In addition to fear and stigma attached to sex and sex work there is one more issue. In our society anything related to sex is shrouded with mysticism and STI disease is no exception. A section of self professed nonqualified sexologist has augmented this phenomenon through their day to day practices. So a conscious effort has to be made by the program implementers to demystify STI management services. Community members should be allowed to develop their knowledge, skill, and aptitude to know and learn about the science of sex and sexually transmitted illnesses including STI management related issues and challenges. Right from the beginning program implements must involve selected number of peer workers in the STI management team, with a view to built their capacity. They can be trained to deal with history taking, maintenance of outdoor registers in addition to follow-up of cases. They need to comprehend basics of lab techniques and procedures. All these efforts enable community members to play their role not just as recipient of services but an able member of the community to help improving treatment seeking behavior of the sex worker through sharing information, counseling, and follow-up of cases. This sort of activities help

demystifying STI management services and help staff members and consumer of services to develop a healthy attitude towards sex and sexually transmitted diseases.

## Deconstruction of STI Management Services

Both outreach and medical personnel working in the clinic jointly develop STI services. Essentially, it is the peer workers who motivate community members to access STI services. They counsel patients to ensure adherence to treatment, encourage for regular use of condom, and facilitate partner's treatment. All these in combination constitute STD management. Partner's treatment, the most difficult component of the STI management services can be improved to a large extent through delegating responsibility to the outreach team, who could influence the sex workers to encourage and bring her partner for availing STI treatment. Development and delivery of different elements of STI services are made through the engagement of a group of professionals and community members ranging from doctors, peers, counselors, and outreach workers. All of them are not placed in the clinic, neither they perform their respective role sitting in one place. However, all members share specific role and responsibilities in creating and delivering STI services. This comprehension helps deconstructing STI management mechanism including its delivery.

## Democratization of STI Management Services (Issues of Governance)

Accessibility and utilization of STI services by the sex worker depends on varieties of internal and external factors which includes development of service delivery mechanism including its approaches. Improvement of quality of STI management services cannot be made possible without having an effective coordinating mechanism between the members of STI management team. The program planner needs to develop adequate system to help share and reflect on clinic based output with the inputs of the outreach team and their findings. Both categories of staff members should share a common platform in terms of their rights and shared responsibilities. It needs to be reflected both in monitoring as well as in the evaluation system of the STI services. (This has been amply explained in clinical governance and audit section.) Regular meeting and sharing of information has to be organized in between outreach and clinical team to improve the quality of services including midterm correction. An open transparent and formal communication channel is required to ensure regular feedback, analysis of data, presentation of cases, etc. to keep track on quality and effectiveness of the ongoing STD management program and its impact on the community.

Designing a model for comprehensive management of STI in sex worker community should address the following challenges.

### Reaching Out to the Community

By and large, in most countries sex work is seen as an illegal trade. In order to protect itself, the trade stays "hidden". This

makes it very difficult to identify and reach out to its members. Some countries have sought to identify sex workers through a system of "registration" of either brothel or sex workers. This has its own limitations, as it creates a distinction between "officially recognized" sex workers for whom there may be some services, and those not recognized will still fall outside the safety net of services. New strategies are required that will reach out to all sex workers, based not on registration but on the right to services and well-being, and which will encourage their participation.

Moreover, as sex work is considered immoral, mainstream society pretends that this trade does not exist and turns a blind eye to it, ignoring it in many ways including the provision of services. In many country-settings, laws and rules are framed such that they criminalize not only sex work but also the entire environment around it.<sup>16,17</sup> All these factors, in combination, make reaching sex workers a formidable challenge. In many countries, although sex work is not illegal, laws are ambiguous, and their interpretation is left to the law enforcers such as policemen and local goons.

Levels of social tolerance and existing legal tools influence the structure of sex trade in different settings, e.g., whether it is recognized, whether brothels are registered or not, whether sex work is practiced as residence-based, hotel-based, street-based, or disguised as massage parlors, escort services, etc. In the recent past the use of mobile phone has become the most preferred channel of communication through which sex worker or clients fix appointments and clients pick up sex workers from the designated sites making it more difficult to reach out to them.

Factors that determine the structure and functioning of sex trade predominantly control sexual practices. So it is of paramount importance to focus on all these interdependent structural factors while developing STI prevention and control program and its strategies.

### Making Services Accessible

There are several barriers that sex workers face in attempting to access STI treatment. These ranges from lack of information and the necessary familiarity to use a service, mobility, distance, purchasing power, location of clinics, and timing of services. The barriers are not only physical but include the strict control imposed by the sex trade controller. For example, the madams or owners of the brothel/hotel strictly limit the mobility of sex workers and do not allow them to go out. Frequent police raids further restrict their movement. Graph presented in Figure 95.1 shows how police raids made it difficult for peer educators to reach out to sex workers vis-à-vis the use of condom and other preventive or care related services.

Local goons can impose their own modalities, including restrictions on where the women can go, and for what reasons. In order to maintain total control these manipulators do not allow the women to mix with others who may provide them information and access to the external world.

**Fig. 95.1:** Graph—police arrest vs. field contact. *Source:* Presentation by Ashodaya Samithi (Mysore) at the National Consultation held at Delhi, November 2007.

### Making Services Acceptable

The availability of a medically sound service is not enough to promote its use by sex workers. A positive attempt has to be made to make it acceptable. An acceptable service is one where the special needs of sex workers are respected.

The service must uphold the dignity and respect of the patient. A sex worker attending a service does so as a patient, not as a sex worker. Yet, often she is treated with stigma and discrimination; staff is disrespectful and makes comments that are highly inappropriate in a healthcare setting, with references made to her occupation and her behavior. All these serve as deterrents to seek treatment and pose barriers to full and effective STI management.

Like any other person, sex workers require privacy and confidentiality in seeking STI services. In their case, the breach of confidentiality can seriously impair their ability to draw clients and earn their livelihood.

### Creating Enabling Environment

Sex work is an occupation for a certain group of women, who maintain their livelihood through this activity. Considering this activity as an occupation broadens the scope of prevention and treatment programs to extend beyond individual medical treatment and take account of determinants that usually lie beyond the purview of medical treatment. This includes environmental factors, which influence or control the sex occupation, trade, and practices in a given context. The laws related to sex trade, the way society views sex, sexuality, and sex work also determine an individual's ability to protect oneself, prevent infection, or use treatment services.<sup>17,18</sup> Other environmental factors that increase risk and violence in the brothel or in the street from hooligans and the police. The high mobility of sex workers is an important barrier making completion of treatment a difficult proposition. Attempts by a section of civil society organizations including government department to enforce rehabilitation program for sex workers against their will poses difficulties in carrying out effective STI intervention program both in brothel as well as in street settings. So there is a need to create a supportive environment for the sex workers so that they feel comfortable to

access services without any fear and apprehension. Program has to incorporate appropriate advocacy element with the police and the administration as part of building supportive environment for the communities. Indian National AIDS Control Program (NACP) with a view to enhance target communities' access and utilization to HIV/STI prevention and care services introduced the concept of 'creating enabling environment' as an integral component of intervention program during the 2nd phase of intervention (2000–2005) and strengthened it further in its 3rd phase spreading from 2005 to 2012 through providing appropriate budgetary allocation to carry out advocacy related activities, with various stakeholders including police and administration. In addition to that National Program added another component to enable and empower communities so that they can access and utilize all relevant preventive and care services including STI services. Indian National Program has fixed a target to reach out to 1.2 million female sex workers with quality HIV and STI services and making it accessible, acceptable, and utilizable by the community member to stall the HIV epidemic in the country.<sup>19</sup>

### Marginal Status

Forced to live on the margins of society and often denied access to basic services, sex workers have very little access to the common pool of information and social services, including health services that the general population can use. This is a great paradox, as the sex workers, as mentioned earlier, require information and services more than the rest of the population. Attempts to bring them into contact with and to make them use the existing services hardly work due to various sociocultural factors besides resistance and discriminatory practices often meted out by the mainstream society and service providers. Hence, it is important to develop specially designed delivery systems looking from the perspective and the social position of the community.

### Stigma

Most societies attach stigma to sex and sexuality, and this stigma is transferred onto all activities associated with sex, other than procreation. The stigma is most pronounced when sex is exchanged for money, involves multiple partners, and is seen as a threat to social and family stability. Sex work then meets all possible criteria for stigmatization.

As a result of this stigma, sex workers are in effect denied even a range of basic services, including sanitation and water supply. Further, the usual attempts to regulate the conditions of work, labor and its environment, now well-established and accepted in most work situations, are not usually applied to sex work in most countries.

### Gender Inequality

In the case of female sex workers, the clients are almost always male. The unequal power relations between the sexes prevent them from effectively negotiating condom use and safer sex, thereby increasing the risk of transmission of STIs. Sex trade is primarily

controlled by a number of stake holders who are in general male. Sex trade is regulated by the law which is often biased against women thereby pushing sex workers to live at the margins of the society. This unequal gender and social status affects their self esteem and confidence to access and utilize relevant STI related services including social entitlements.

## DESIGNING AN STI MANAGEMENT PROGRAM

Four elements that need to be considered in designing an STI control program are:

- Familiarity with the epidemiological patterns and physical and social set-up of the community,
- Development of a service delivery mechanism,
- Development of capacity, and
- Monitoring and supervision.

## Epidemiological Patterns and Set-Up

Data on epidemiological trends and disease profile can be collected from available sources or extrapolated from other similar settings. Information related to the structure and functioning of the sex trade, including specific patterns such as timing, control by different agents and nature of the sex-service delivery settings, e.g., street-based brothel or hotel based, should be collected. Mapping of sex worker would help estimating sex workers population, volume of sex work, types and nature of sex practices, use of condom, etc. The availability and quality of healthcare services, particularly for STIs, and how the community uses them is also essential information. Finally, an understanding of the legal provisions and instruments in the country and how they are implemented in the specific community is useful,<sup>18</sup> for example, in Bangladesh brothel-based sex work is legal; however, it is strictly controlled by the local goons with the collusion of the police. Sex workers have very little autonomy to act in accordance with their own decisions and wishes. Whereas in Thailand, although it is illegal, government and administration are very tolerant of this trade and have adopted a 100% condom use policy through brothel owners with a view to address the HIV epidemic and STI prevention.<sup>20</sup> The 100% Condom Use Program in Thailand has created an opportunity for sex workers to avail and access condom and STI services.<sup>21</sup>

## Service Delivery Mechanism

An effective STI management program addresses prevention and cure simultaneously. The need for partner notification and secondary prevention in sex workers with proven STIs is paramount, while this can be challenging at times. Second, it has to take into account the structure and functioning of the sex trade in that setting. Norms and practices of the sex trade differ—in some places it is a daytime trade, in others it is at night. In some places it is madam-controlled, in others it is controlled by hotel managers, in yet others the women are self-employed. The process

of setting up and managing a service will depend on these and other similar contextual factors. Third, the community of sex workers must be involved from the very beginning in designing and implementing the service. They are an intrinsic part of the solution, as they have the best insight into the situation.

The community involvement has to be incremental over a period of time, based on increasing capacity, confidence and trust. Hence building trust with the sex-workers community is a very important issue at the start of developing a service.

Development of STI service delivery system needs to be considered at two levels: level-1 through outreach component of the program, and level-2 through establishment of a clinical outlet.

## Outreach

An outreach component primarily addresses issues of access and acceptability but will also share responsibility in connection with follow-up of cases, directly observed treatment (DOT), counseling, and partner treatment.

Experience shows that a peer-based outreach program is the most effective model for marginalized and hidden subpopulations.<sup>13,22</sup> Peers can bridge the gap between marginal populations and mainstream services and service providers. They can overcome the cultural barrier in communication. In most circumstances, peers are the best possible agent to reach the hidden population. Through peers, the involvement of the community can be initiated and strengthened, and trust built.

**Peer Led Outreach** Recruiting peers should be based on a clear understanding of their role. Selection of peers should be based on their interest, commitment, verbal communication skills and their acceptability to the community, and not on formal education or age. Self-employed women are likely to be more effective, as in Sonagachi, Kolkata and Tangail, Bangladesh, as they have more autonomy.<sup>6,13</sup> The major task of peers is to deliver a package of preventive and curative services to the end-users. To begin with, they can concentrate on providing preventive messages, the delivery of necessary equipment for prevention (e.g., condoms, spermicides/microbicides) and encouraging the sex workers to effectively negotiate safer sex. They can also assist sex workers to use clinical services and can facilitate overcoming the resistance from the controllers of the sex trade. Gradually, based on the development of requisite skills and experience they will be engaged in improving compliance with treatment regimens, identifying any side effects or problems in taking treatment, and reporting back to the clinic. In spite of limited education, they can effectively maintain records through innovative methods. These records form the basis of the monitoring and information system. Finally, in the third phase, they can be involved in the clinic setting for medical history taking (particularly sexual), drawing of blood samples, physical check-up (weight, blood pressure, and ulcers), and follow-up of patients and administration of DOTs. Following the peer outreach model of Sonagachi intervention program, the Bill and Melinda Gates Foundation developed

an effective intervention in six high prevalence states in India during 2003–2010 covering around three hundred thousands sex workers population through establishing around 370 STI management clinics closest to sex work sites. This is known as AVAHAN program, which adopted community mobilization as the core strategy followed by introduction of peer led outreach and provision of STI services in addition to advocacy component as part of the intervention program. AVAHAN achieved favorable outcome both in stabilizing HIV and STIs among the female sex workers in those intervention areas.<sup>23</sup>

### Setting Up a Clinic

The design of the service delivery mechanism will depend on the type of sex trade—it will vary from brothel-based to street-based. Provision of clinical services through a fixed facility or a mobile clinic or within a drop-in center will be decided based on the setting and availability of resources.

Experience shows that a fixed clinic arranged within or in the vicinity of a red-light district is best suited for a brothel setting as it provides a relatively safe and comfortable social environment for sex workers to come together even for reasons other than STI treatment alone.<sup>14</sup> A clinic within the area of the brothel overcomes barriers related to mobility and restrictions imposed by sex-trade controllers. In case of street-settings, a drop-in center provides a similar opportunity where street-based sex workers can come and relax, and meet other needs including that for STI treatment.

They are more likely to use a center, which meets multiple needs, rather than find the time and opportunity to prioritize only STI treatment. In addition, the drop-in center can also provide the space to organize education sessions reinforcing STI prevention and treatment.

The difficulties faced in setting up a special clinic or drop-in center include limited resources, difficulty in renting an appropriate space and on the part of medical professionals regarding working in such an area and also the practical problems of working at odd hours of the day or night.

A STI clinic is often seen as stigmatized and persons who are availing its services are shy to do so. This applies to sex workers as well; they are not comfortable about going to an STI clinic. Experience from Sonagachi,<sup>13</sup> Kolkata and from other parts of the world confirmed that locating the STI services within a general health clinic is more acceptable. In addition, it meets the other health needs of sex workers and their families. As children and older persons also use the services, it gets less and less associated with sex workers and the stigma is reduced. Over the years, there is a possibility that the clinic will be crowded with patients with general complaints. To overcome this situation and promote greater emphasis on STI, a plan is required. This could be based, for example, on the pricing of services—STI consultation could be free and medication given at a subsidized cost, while general ailments are charged and medication has to be paid for. The timing of the services could be such that the timing allocated for

general services is restricted, while STI treatment is available at all times. People may therefore prefer to seek general treatment from elsewhere.

**Staffing the Clinic** The attitude of the staff towards the sex worker is an extremely important factor to be considered in recruitment. As long as there is a basic acceptance of human beings and openness of mind, the appropriate nonjudgmental attitude of respect can be developed.

Confidentiality requires special attention in this setting. Healthcare providers should not be less serious about maintaining the confidentiality of sex workers. There is a myth that sex workers are “shameless” and therefore do not require discretion and privacy in matters relating to sex and sexual health. Confidentiality must be maintained during history-taking and examination, during disclosure of diagnosis, and maintenance of patient records and files. A system to ensure that confidentiality is maintained at all times has to be installed as otherwise it will depend on individual inclination and cannot be assured.

This system should include specifications regarding physical privacy (a private, secluded space for history taking, examination, privacy during counseling), home and community visits, and maintaining patient records (anonymity of patients in records, and restriction of access to records only to those who must see them for management of the case). As the sex trade is not really legal, police and other law enforcers might wish to track a particular sex worker and ask to see records. The health department may also make demands of this nature, saying it is in the interest of disease control. While establishing the clinic these challenges have to be considered and an arrangement worked out with the necessary public offices to ensure that clinic staff is not pressurized in this regard. Simultaneously, the staff must be well aware of these issues and have the necessary papers, permissions and policy guidelines to support their efforts to maintain confidentiality.

Each clinic should develop a code of medical ethics regarding confidentiality and privacy with respect to STI patients and their partners. This is especially important as partner tracing and treatment is an integral part of effective management. It is necessary to recognize the resistance of partners to visit a clinic meant for sex workers, as the social stigma of being identified as a partner of a sex worker is very high.<sup>8,24</sup> A different service outlet and approach for dealing with the partners of sex workers may therefore be necessary, and every effort should be made to establish linkages for this service.

In addition to the delivery of STI services, the center/clinic should provide a setting for training and upgrading the skills of all staff and of the community.

**Case Management Strategy** In the last decade, several strategies for case management have been tried in different parts of the world. Traditional clinical diagnosis with or without laboratory support and its limitations in different settings forced the scientific community to consider other options such as syndrome based management of major STIs, mass treatment, screening followed by treatment, and a combination of these. There is no single

answer to the question of which is the best approach, as each has its merits and limitations.

The “best approach” also depends on the level of development of STI services in the country, the availability and quality of laboratory services, appropriate human resources, and availability of financial resources. The advantages and disadvantages of each approach in dealing with STIs among female sex workers are discussed below.

The efficacy and efficiency of orthodox clinical diagnosis and treatment has proved to be the lowest. The entire approach depends solely on the individual medical physicians, and their skill to diagnose STI cases based on clinical acumen. The approach is neither standardized nor very sensitive. Wrong diagnosis and inappropriate choice of treatment regimens not only make treatment ineffective but lead to the development of drug-resistant strains of organisms over a period of time. This approach has very little place in the development of STI management programs for sex workers.

**Syndrome-based management:** The advantage of this approach is that a group of symptoms are clubbed together as a syndrome, and treatment is provided to address all the possible infections which cause these symptoms. The choice of treatment regimen does neither depend on individual judgment, nor does it depend on the specialized clinical skill of individuals. The treatment regimen can be standardized according to the prevalence of disease patterns in specific communities and the availability of drugs.<sup>16</sup> The most important advantage is that less qualified personnel can be trained to safely and effectively practice this approach, reaching a higher proportion of patients with better services. This approach provides a greater scope for training even to sex workers/peers in providing the different components of the treatment process, for example, history taking follow-up of cases and ensuring compliance. One of the major limitations of syndrome-based management for sex workers is that the most common clinical symptom in women is vaginal discharge, and it is neither sensitive nor always specific to STIs. A recent review of this approach has indicated that syndromic algorithms have shortcomings, and they should be periodically revised and adapted to the epidemiological patterns of STIs in a given setting.<sup>25,26</sup>

**Etiological approach:** The advantage of the etiological approach is that the patient gets specific treatment for a specific ailment, provided the process of diagnosis and treatment regimen receives quality laboratory support. Therefore, there is less chance of overmedication and indiscriminate use of drugs. The disadvantage is that the patient has to wait for the results of laboratory tests before treatment can be started thereby increasing the risk of transmission of disease during this period. This is an extremely important limitation in a sex work setting where risk of transmission to several people, even within a day seriously compromises the value of this approach for community-based STI programs. While high cost and delay in the availability of results have restricted the use of this option, particularly for sex worker settings, making laboratory services accessible has

presented an additional challenge. However, there has been considerable effort to develop appropriate laboratory based STI diagnosis in the recent past, to deal with symptomatic and asymptomatic presentation of STIs. Non availability of quality laboratory services is a major challenge to implement this approach. However, there is an increasing trend and availability of relatively low cost point of care testing globally. This technological development has cut down the waiting period drastically. As a result of which this approach proved to be beneficial to sex workers in terms of increase in attendance and optimum use of medicine. The global view has been steadily shifting towards laboratory based diagnosis of STI both in the developed as well as in developing countries. There is very little doubt about the emergence of consensus that rapid point of testing of STIs is the way forward in every STI service settings. This approach needs to be made available to sex workers.<sup>15</sup>

One of the major limitations of all the three approaches described earlier is that they only cover symptomatic cases and of these, only those who seek treatment. Major STIs such as syphilis and gonorrhea in females are often (in about 60–80% patients) asymptomatic; this is a problem for partner treatment too. The new developments in STI diagnosis, as indicated above, can be particularly suitable for screening STIs among sex workers.

**Mass treatment:** It implies treating all members of a community, assuming that the infection is widespread. This treatment can be done at regular intervals (biannually or annually). The basic objective is to reduce the pool of STIs in the population at a given point of time, thereby cutting the channel of transmission. The advantage of this approach is that it is simple to administer from the technical point of view. The cost is less over a period of time (compared to clinic-based etiological treatment). Logistically mass treatment can be delivered through a camp-approach, reducing investment in infrastructure and recurring staff costs. This approach also covers many asymptomatic persons who may have infection(s) but will not seek treatment. The limitation of this approach is that where the sexual partner exchange rate is high and the partner stays outside the geographic catchments area, reinfection is common and mass treatment will thus be futile. This approach limits provider-patient dialogue and opportunities for counseling on the preventive aspects. Opportunities for sex-worker community involvement are minimal, and the approach may be viewed as an external initiative, impinging on their rights and choices. Over-treatment is also a limitation. The use of mass treatment in isolation in a sex-work setting therefore cannot be recommended.

However, it can be tried in combination with another approach, e.g., mass treatment followed by syndrome based management of cases or making arrangement of point of care testing in clinic set up dedicated to sex worker population.

**Screening and treatment:** Mass screening of the community members followed by selective treatment is a possible option. At what interval and how this is to be done remains an issue. The advantage of this approach is that it is specific, it can reach

asymptomatic cases, and it reduces the indiscriminate use of drugs. The biggest obstacle is the availability of quality laboratory services for large-scale screening of all major STIs, the prohibitive cost, and the logistics of applying the screening and subsequent follow-up treatment. The option is further compromised in case of sex workers because of the high frequency of partner change and possible exposure to infection on a daily basis. However, the introduction of opportunistic screening among clinic-attendees could improve both the quality of clinic-based service as well as the delivery mechanism by incorporating a percentage of asymptomatic cases.<sup>27,28</sup> Based on the previous discussion about STI management in sex worker populations and the experience gathered in different settings, the authors would like to recommend a fixed general clinic setting with specific emphasis on STI management. The clinic should provide a clear demonstration of condom use in addition to providing condoms. Counseling services should also be made available to clinic attendees to clarify doubts and reinforce messages regarding safer sex. The culture of the clinic should be warm and welcoming, not judgmental, threatening, and alienating. A syndrome-based approach with the gradual introduction of opportunistic screening for one of the major STIs, for example syphilis, and the provision of simple on-site laboratory testing facilities would be the most effective and sustainable. Depending on the development of the program and its impact on the community, gradually more effective strategies vis-à-vis technologies could be introduced to upgrade the program delivery mechanism, such as the introduction of noninvasive laboratory techniques (e.g., a urine test for chlamydia) for all clinic attendees, thereby effectively widening the treatment net. Any approach should view the context as dynamic and be flexible and foresighted enough to take account of this continuous change.

**Linkage with Service Providers in the Locality** No service operates in a vacuum. There are existing local service providers who feel threatened and will therefore, resist the introduction of a new facility. From the beginning, the program should engage with local private service providers in order to soften their resistance, and help them feel comfortable and involved with the service. An effort must be made to obtain their cooperation and assistance in getting referrals and improving the overall quality of services available in the community. For example, inviting them to visit the clinic, arranging training and workshop programs for traditional and other healers, sharing technical and programmatic materials, can improve the relationship with local private providers. Simultaneously, it is necessary to establish a linkage for referring difficult and resistant cases with STIs as well as for other diseases, which cannot be handled at the community clinic. Linkages with reputed laboratories are also required for assuring quality.

## Development of Capacity

Capacity development is an integral part of quality service delivery. First, STI management is still a developing science in many developing countries. STIs should be managed not only at an individual case level, but also at the community level.

Managing STDs at the community level is a challenge because it requires the appropriate mix of skills (as described above) and availability of technology. Second, as existing research proposes an incremental involvement and ownership of the community, it is extremely important to draw guidelines, develop policy and strategy for capacity development of different categories of staff including community members. These should take into account the dynamic context and changing diagnostic tools as well as advances in biomedical intervention. At all points capacity-building is to be viewed as a two-way process where the management including professionals and the community learn from each other in a “learning” atmosphere; it is not the mere transfer of knowledge from top to down in a hierarchical manner.

## Technical Capacity Building

As prevention and care goes hand in hand, all members of the team should have good communication skills in dealing with clients. Staff, including peers from the sex worker community should be acquainted with the newer developments and their implications in their on going program.

The implementers should try to open a dialogue regarding the relevance and appropriateness of the technology for the on-going activities. Besides, the team should be encouraged to acquire skills in critically examining and analyzing the context, e.g., the role of madams and pimps in determining access to service or that of local healthcare providers.

## Monitoring and Supervision

Supervision should be a joint process involving the sex worker community as well as professional staff and management. Usually, supervision and monitoring is seen as a top-down, technical issue that can only be undertaken by highly qualified professionals. On the other hand, experience from different programs has demonstrated the efficacy of community participation. As an STI and sexual practice is such a private issue, whatever the professional skills and tools, they are barely adequate to secure quality information. Representatives of the sex workers, on the other hand, due to their close relationship of trust and deep understanding of the nuances of the business are able to get more accurate and complex information. Importantly, systematic collection of basic data is crucial to inform the program. This included annual mapping of sex establishments and enumeration of sex workers, behavior monitoring (focusing on condom use and number of clients), and STI screening. Monitoring activities would be largely built into the day-to-day activities of the STI clinics, and few special surveys may be required to comprehend service utilization pattern, client’s satisfaction, etc.

Appropriate user-friendly tools can be developed that allow recording and sharing of critical information with the sex trade community, e.g., diagrams indicating access to treatment and condom use through outreach, which are then displayed at the clinic or shared in other ways. This creates a mechanism for regular feedback.

Indicators for the outreach component as well as the clinic component should be correlated and examined for a match at regular intervals. This matching exercise will strengthen the robustness and validity of the information, as well as identify areas that require further attention and indicate where there is inaccurate or incomplete reporting and recording.

## CLINICAL GOVERNANCE, CLINICAL AUDIT, CLINICAL UPDATES

Clinical governance is a system through which clinical service organizations are accountable for continuously improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish. World Health Organization describes clinical governance as professional performance (technical quality), resource use (efficiency), risk management (the risk of injury or illness associated with the service provided), and patients' satisfaction with the service provided.

The technical quality of STI services for sex workers can be assessed by clinical audit. An in-built system of clinical audit must be a part of the STI management program. A robust evidence-based auditable clinical outcomes should be established. Regular clinical audit cycles should be conducted to assess adherence to the clinical guidelines on a routine basis. The audit should look into regular and complete recording of patient's sexual and reproductive history and diagnosis, the adherence to treatment guidelines (e.g., closely following the standard flowchart for treatment, adopted by the program). The audit will also enquire into client satisfaction, effective communication between doctor and patient (e.g., whether patients understand the treatment regimen and could express difficulties in following treatment directives). This process examines the performance of all categories of staff in an open and transparent manner, allowing each one to reflect on their work and to identify steps to rectify shortfalls themselves, without blame. It further reiterates the value of the contribution of each and every staff. This process empowers different categories of staff and essentially breaks the hierarchical structure in favor of a more horizontal one.

Clinical update will involve reevaluating-service training, multi-disciplinary team meeting to discuss difficult clinical cases, journal clubs, attending conferences and other learning opportunities. There should also be learning facilitation utilizing external agencies, at least annually. Exchange visits with other relevant institutions are also highly recommended.

## Conclusion

The approach towards STI management presented in this chapter looks at the issue in a wider perspective—that of management of STIs at a sex-worker community level, rather than only at an individual patient or case level. The intention is not to undermine the role of medical professionals, as the value of their expertise is clearly irreplaceable. Their role would be viewed as leaders of a multidisciplinary team where the active

involvement of the community is essential. In the past purely biomedical approach has been limited in dealing with the various barriers to effective treatment seeking behavior and practices, including primary prevention. The authors have tried to highlight the importance of long-term sustainability through fostering community involvement and ownership. Medical professionals have a responsibility as well as an important role in building appropriate capacity in the community and in re-examining their own values and practices through a process of sharing and learning. As team-leader, medical professionals have to use their expertise in finding the best specific solution and designing the best suited services for each context—there is no single “model” that is ideal in all settings.

Community management of STIs in sex workers cannot follow a prescriptive model. The situation is in a state of constant development and flux and so is the level of knowledge and technology. An effective strategy is one where this changing scenario is recognized and re-examined regularly and the program is accordingly restructured and revised. One needs to be open to newer strategies and tools of interventions, e.g., voucher scheme, opportunistic screening, point of care testing etc., and would decide to include or exclude those based on the perspective of sex work settings and availability of tools and finances.<sup>28–30</sup> In this respect, the clear direction of travel towards low cost point of care testing is increasingly adopted globally. This could improve the quality of care for STIs in female sex workers, who are increasingly valuing this approach.

The dynamism within the community of sex workers also influences the outcome of the program. The responsibility of the team-leader includes being fully aware of these forces and the ability to make necessary adjustments in the program. Keeping in view the aspirations and skill development in the community, there will be a need to modify and upgrade the program periodically.

One of the major challenges the team-leader faces is the low priority and stigma that STI management receives within and across the medical world. Some efforts have to be made to influence policy-makers and leaders, including the medical community to change attitudes towards sex and sexuality and STIs.

# Sexually Transmitted Infections Associated with Sexual Assault

P. Janet Say

96

## Introduction

Sexual assault is defined as an act of a sexual nature on another person without their consent. It can range from fondling to forcible penetration, and may often, particularly in the sexual assaulted adult males, be associated with other physical violence. It may involve the use, or threat of force or maybe performed on a victim unable to give consent because of their age and/or physical or mental disability.<sup>1</sup> Different countries have different legal categories of sexual assault. The different definitions can range from terms such as unlawful sexual connection to “eve teasing” and there are often differences between male and female sexual assault legal nomenclature. These categories are necessary to define the gravity of the offence and guide subsequent sentencing.

Sexually transmitted infections (STIs) are often an unwanted consequence following sexual assault. The possibility of HIV transmission during the sexual assault has further added to the panic and stress related to sexual victimization.<sup>2</sup>

Both male and female, adult and child, victims of sexual abuse are at risk of acquiring a sexually transmitted infection. Doctors examining and treating such patients require knowledge of STIs on which to base their clinical care and forensic opinion. The brief notes provided in this chapter are not, however, a substitute for keeping up-to-date with the current literature in this rapidly expanding field. Optimal management of STIs, particularly in children, may also require consultation with a specialist in sexual health as well as pediatricians.

## Epidemiology of Sexual Assault

Only a minority of sexually abused children in developing countries receive a medical examination, which includes optimal STI screening. The same is true for adult victims of abuse—only a very small percentage of whom ever present to an official agency.<sup>3</sup> In the USA for every sexual assault reported, 3–10 are unreported, one in 3 women worldwide has experienced sexual assault or rape.<sup>4</sup> The criminal offence of rape in marriage is being increasingly recognized in developing countries, e.g., India.

One in 6 or 7 rape victims in the USA are male.<sup>5</sup> An analysis of 120 studies of prevalence of sexual assault in the USA showed 13% of women and over 3% of men reported being raped. Attempted rape was reported in 18% of women and 6% of men, and sexual assault was reported by 22% of women and 14% of men.<sup>6</sup>

## Epidemiology of STI in Sexually Assaulted Adults

In an adult who has a history of consenting sexual activity it may be difficult to attribute the acquisition of the STI from an alleged offender. Gonorrhea, Chlamydia, and *Trichomonas* in women are often asymptomatic and can be pre-existing before the event.

Davis<sup>7</sup> showed that of 110 women seen at the Sexually Transmitted Infection Clinic in Birmingham, UK, who claimed to have been raped, 14% had STIs, of which 8% had chlamydia and 6% *Trichomonas*. Wintle's audit in Auckland showed 11.9% had an STI with 6/109 women undergoing a forensic examination having chlamydia, gonorrhea or both infections.<sup>8</sup>

The risk of acquiring an STI consequent to sexual abuse varies with the disease prevalence among offenders and the nature of the sexual contact. The factors which influence disease prevalence among offenders include its prevalence in the general population, the local incidence of disease, and the incidence of particular infections in high-risk activity groups (e.g., hepatitis B virus, HIV). The factors related to the sexual act which affect the risk of acquiring an STI include the nature of the sexual act (e.g., vaginal or anal penetration), the degree of trauma present, and whether body fluids were exchanged.

The most likely infections for which these patients are at risk appear to be genital warts, chlamydia, gonorrhea, genital herpes, trichomoniasis, syphilis, and HIV.<sup>9</sup> All these infections (except HPV) are now documented in various studies to be associated with a higher risk for acquisition of HIV.

## Sexual Assault in Adult Males

Anal penetration occurs more commonly in male rape with skin and mucosal damage occurring in up to two-third of victims,<sup>10,11,12</sup>

and thus males are at a higher risk of acquiring infections such as hepatitis B virus and HIV. De Visser reports on experiences of sexual coercion among a representative sample of adults. A telephone interview was completed on 10,173 men and 9134 women aged 16–59 years with a response rate of 73.1%. In the study 4.8% of men and 21.1% of women had experienced sexual coercion and 2.8% of men and 10.3% of women had been coerced when aged 16 or younger. Adverse outcomes in males included increased risk of history of STIs, increased smoking, and drug use as well as avoidance of sex. 2.6% of males compared to 7.3% of females reported to the police.<sup>13</sup>

Men who have sex with men (MSM) were 5 times more likely than heterosexual males to have suffered sexual assault and this is possibly related to their higher number of partners, the situations in which they seek sex, and the phenomenon of gay bashing. Overall most males were less likely to present to health agencies for disclosure because sexual assault is generally thought to be a female issue; it infers a loss of masculinity or male weakness and the possibility of being labeled homosexual.<sup>14</sup> Sexual identity and orientation can be confused and sexual dysfunction may follow. It is common for arousal, even ejaculation, to occur in males who are groomed during the assault.<sup>15</sup>

A single episode of receptive anal intercourse with an HIV-positive male in Australasia has a risk of approximately 1 in 100–200 of transmission of HIV compared to insertive anal and vaginal intercourse of 1:1000, but HIV post exposure prophylaxis (PEP) should be offered in these situations.<sup>16,17</sup>

Reeves et al. report on a review of the forensic notes on 92 males in London of those 30% were heterosexual and 34% were homosexual; there was no information regarding the rest. The majority (79) were referred to the police. Non genital injuries were documented in 40% and anal injuries in 34%. HIV PEP was commenced in 23 of the 54 men reporting rape and 14 of the 31 with anal injuries.<sup>18</sup>

A telephone interview study of 8005 males and 8000 females in USA confirmed that 219 males had been sexually assaulted, a prevalence of 3%. 11% had undergone physical violence, 31% had been raped anally, and in 5% weapons were part of the attack, 29% sought help but only 19% reported to the police.<sup>19</sup>

## Epidemiology of Sexual Assault in Resource Poor Nations

The World Health Organization (WHO)<sup>20</sup> has recognized the importance of sexual assault in the spread of HIV particularly in Third World countries where the disease may be endemic and multiple economical, sociocultural factors add to the risk of its spread.<sup>21</sup> In undeveloped nations intimate partner violence (IPV)<sup>22–24</sup> may not be acknowledged let alone legislated for. Many countries are war zones and rape may be part of torture of females<sup>25</sup> as well as males.<sup>26</sup> Coercion is as common as much as in developed nations, but the imbalance of power in many countries between males and females is a very important factor.<sup>27</sup> Poverty is a driving force for “survival

sex” in street kids, the trafficking of children into sexual slavery and also it encourages the “sugar daddy” phenomenon, as in Africa. In a study of HIV prevalence in sex trafficked Nepalese girls 38% tested positive for HIV and the median age of trafficking was 17 years with 14.7% trafficked before the age of 15 years. Those under 15 years were at increased risk of HIV, particularly if they were trafficked to Mumbai.<sup>28</sup>

Childhood sexual abuse (CSA) has been quoted as less than 4% overall in China, but in Chen’s paper 1 in 5 young women (21.9%) reported at least one type of child sexual abuse before the age of 16 years.<sup>29</sup>

Lalor’s literature review of child sexual abuse (CSA) in sub-Saharan Africa estimated that approximately 0.6–1.8% of all children in high HIV incidence countries in South Africa would experience penetrative sexual abuse by an AIDS/HIV infected perpetrator before 18 years of age. This would be in comparison to Ireland where the risk is 0.004%.<sup>30</sup> The same author described how CSA had increased in Tanzania possibly because of the idea that one “may cleanse” oneself of AIDS and other STDs by having intercourse with a virgin or young girl. Sixty five per cent of Tanzanian members of parliament felt that witch doctors were making defilement of children or incest a condition for their customers in obtaining wealth or solving their problems.<sup>31</sup>

Worku et al. studied childhood sexual abuse and its outcomes in female high school students in Ethiopia and of 323 students, 68.7% reported CSA, 7.2% of these had an unwanted pregnancy, and 5.9% had sexually transmitted diseases.<sup>32</sup>

The WHO is concerned at the effect of IPV and sexual violence on the HIV epidemic. An expert meeting occurred in May 2007 to discuss measures of prevention and tabulated the factors associated with IPV for the victim and the perpetrator as well as those associated with sexual violence.<sup>33</sup>

More than 1 in 3 married Bangladeshi men reported physically and/or sexually abusing their wives in the past year. They were also more likely to report both premarital and extramarital sex partners. On top of that they were less likely to disclose STI symptoms or infection to their wives, i.e., discharge from the penis, a sore or ulcer on the penis, or dysuria in the past year.<sup>34</sup>

A study from Goa in India concluded that socioeconomic deprivation and gender disadvantage were associated with a raised risk of reproductive tract infections, e.g., bacterial vaginosis (BV). The risk factors for STIs included the indication that disadvantaged women were likely to be infected by their husbands.<sup>35</sup>

Similarly, a further longitudinal study in women in Goa showed that spousal sexual violence and poverty were risk factors for incident STIs in women. Of 2180 women followed up 101 (4%) had an STI at baseline. At 6 months 37 (1.8%) had an STI, chlamydia (13), gonorrhea (14), trichomonas (9) and one had both gonorrhea and chlamydia.

At the 12-month visit 991 women were screened and 28, i.e., 1.4% had an incident STI, chlamydia (9), gonorrhea (8),

trichomonas (10) and one with dual gonorrhea and chlamydia. The findings support the previous cross sectional study that women were likely to be infected by their husbands.<sup>23</sup> In other studies this has included acquisition of HIV infection by married, monogamous women in India.<sup>36</sup>

Acute trauma following sexual assault can lead to complications such as labial adhesions.<sup>37</sup> A study of 4715 women and girls who had suffered sexual violence in the Congo between 2003 and 2006 showed 702 had been left with genital fistulae.<sup>38</sup>

## Alleged Offenders

The incidence of STIs in alleged offenders is unknown as it is unusual for them to be examined. Giedinghagen<sup>39</sup> described a group of 75 children where their alleged offenders were examined for gonorrhea, 17% of offenders were culture positive. Physicians examining complainants of sexual abuse should encourage the screening of alleged offenders for the presence of STIs. However, consent involving very careful pretest counseling, that is well-documented, should be adhered to because of the legal implications of using evidence against possible offenders. STIs may be more common in some sexual offenders compared to the general population, and screening should be undertaken whenever possible. Detection of an STI will alert the physician to the likelihood of infection in a victim so that appropriate investigation, treatment, and long-term follow-up can be instituted (see Table 96.1). It may also have valuable forensic implications, which may provide corroborative evidence of a sexual assault for care and protection of the child or prosecution of the offender in court.

It will also alert the physician to the need for contact tracing other sexual contacts of the offender (e.g., adult sexual partners, other children in the family) and may result in a guilty plea by an offender thus avoiding the need for a court appearance by the victim. Further it may become an issue in victim compensation if contraction of a specific sexually transmitted disease can be proved to result from an assault. This has become more important with refined methods of DNA finger printing available for epidemiological typing. A negative screening of the alleged offender allows the physician to reassure the victim that the likelihood of having contracted a sexually transmitted disease from the assailant is minimal and may obviate the need for some screening procedures in the victim. It should be remembered, however, that the sensitivity of most diagnostic tests is not 100%. A clinical decision should be made whether to screen a victim despite negative testing of the offender.

## Relevance of Sexually Transmitted Infections in Medical Management of Sexual Abuse

The health of the sexually assaulted individual can be jeopardized if there is no adequate post-assault medical management. The increasing prevalence of viral STIs with long-term complications

are of particular concern because there is, as yet, no curative treatment, and long-term management by physicians with specialized knowledge is required.

Knowledge of STIs is essential for planning assessment and management of patients who have been sexually abused, and includes causative organisms and their incubation periods, clinical syndromes, diagnostic procedures, disease prevalence, relative risk of specific disease acquisition, and interpretation of results including their forensic relevance.

Advice on the risk of acquiring an STI, optimal screening for the presence of an STI (see Table 96.2), optimal timing of such screening (particularly in children when this should be kept to a minimum), advice on prophylaxis for STI, treatment of any diagnosed STI, short-term follow-up including sexual contacts of the patient, long-term follow-up (particularly for viral STIs—onward referrals, where indicated), and screening of alleged perpetrators and their contacts if indicated.

Apart from clinical care, investigation, and treatment, evaluation of victims has forensic implications. Briefly, the presence of certain STIs is one of the most objective indicators of sexual abuse in children and may occasionally be relevant in adult rape. Further, forensic opinion is dependent upon careful adherence to detail

**Table 96.2:** Recommended Optimum Screening for Sexually Transmitted Infections in Adult or Adolescent Women

regarding the chain of evidence and procedures for collection of laboratory specimens. Opinion on the significance of a particular STI in relation to likelihood of sexual abuse may be needed for child protection and judicial agencies (see Chapter 108).

## Sexually Transmitted Infections in Sexually Abused Adults and their Forensic Relevance

### GONORRHEA

The disease affects columnar epithelium of the urethra, throat, rectum, and cervix of adults. The incubation period is 3–5 days in adult males (with urethritis) and up to 14 days or longer in females. Throat, cervical, and rectal infections are often asymptomatic. Acute cystitis may present or pelvic inflammatory disease may develop and lower abdominal pain may be the cause for admittance of a young/adolescent female to a pediatric ward. In low incidence populations infection may have forensic relevance occasionally in adults, particularly in virgins.

### CHLAMYDIA TRACHOMATIS

Infection of *Chlamydia trachomatis* is usually asymptomatic in adult women and post pubertal female adolescents (up to 85%) and 25% in adult/adolescent males.<sup>40</sup>

Anecdotally, *C. trachomatis* has been shown to be present in the cervical mucosa of an adult 6 years after possible acquisition of the organism. It is probably the commonest STI liable to be contracted post sexual assault and prophylaxis should always cover for this infection.

Lymphogranuloma venereum (*C. trachomatis* L<sub>1</sub>, L<sub>2</sub>, L<sub>3</sub>) is now described in many countries in MSM populations, usually as a rectal infection that requires 3 weeks of doxycycline treatment. It has not yet been identified as acquired post sexual assault.

### TRICHOMONAL INFECTION

*Trichomonas vaginalis* is an STI with an incubation period of 7–28 days. It may present late, after gonorrhea or chlamydia diagnosis in women as a green, frothy, fishy smelling discharge. The prevalence of disease increases with age in women. *Trichomonas* in adult women can occasionally be transmitted during sexual assault and rarely has been shown to have forensic relevance.

### SYPHILIS

Syphilis serology should always be done as part of an STI screen associated with sexual assault. Post assault antibiotic prophylaxis against STIs should optimally include an agent which is treponemacidal. In low-risk adult populations syphilis acquisition may be a marker for sexual assault. The person should have follow-up serological screening at 3 months after the last abusive incident.

### HUMAN PAPILLOMAVIRUS (HPV) INFECTIONS (GENITAL WARTS)

Over 150 types of human papillomavirus are known; about 24 types are known to infect genital squamous epithelial cells which undergo transformation and proliferation. The incubation period varies from 4 weeks to 2 years. Cases of genital warts may follow sexual assault in both male and female adults but relating their acquisition to the assault is problematic in most cases.

### VULVOVAGINAL CANDIDIASIS

Asymptomatic vaginal carriage is common in young women and trauma may encourage infection presenting post assault. Candidiasis can produce nonspecific changes, i.e., redness, superficial ulceration, and fissuring that should not be confused with traumatic effects at the acute examination.

### BACTERIAL VAGINOSIS

BV is an overgrowth of many bacteria, particularly anaerobes and mycoplasmas, at the expense of resident lactobacilli.

BV is not yet thought to be a sexually transmitted infection but is associated with sexual activity, consenting or nonconsenting. Prophylactic antibiotic regimens are often used for this common condition post assault.

### GENITAL HERPES INFECTION

The majority of genital infections in adults are caused by HSV-2 virus, although, increasingly common type 1 infection is isolated in the genital region. The incubation period varies from 2 to 20 days (usually 2–5 days). In a previously sexually active adult, forensic relevance is questionable, unless symptoms occur post assault, with seroconversion confirmed by herpes serology.

### HUMAN IMMUNODEFICIENCY VIRUSES (HIV-1, HIV-2)

The incubation period for seroconversion varies from more than 2 weeks up to 2–3 months in the vast majority of cases.

Acquisition of this infection is the most feared sequelae following sexual assault. PEP following sexual assault is available.<sup>16</sup> HIV infection following rape has been reported.<sup>41–43</sup> Hillman<sup>10</sup> pinpointed the need for an increased awareness among the general public of male sexual assault and the increased risk of acquiring HIV infection in this group.

### HIV Prophylaxis after Sexual Assault (PEP) (Table 96.3)

Post exposure prophylaxis should be given optimally within 1 hour and up to 72 hours where there is a high-level exposure to HIV. The risk for acquisition post-rape may depend on the type and length of time of sexual contact, the extent of trauma or presence of STI or genital ulcerative disease in the victim, and the likely incidence of HIV disease and viremic state of the alleged assailant.

In high-risk situations, it is appropriate to administer combination therapy for 4 weeks. Triple therapy is indicated in very high-risk situations.<sup>16</sup> The patient must be fully counseled on the risks of side effects and long-term complications, as well as carefully followed up. Follow-up includes monitoring of side effects, blood tests, and HIV screening at 4 weeks, 3 and 6 months.

Burgess<sup>44</sup> discussed the ethical dilemmas of HIV and rape, concentrating on the need for legislation to protect both the victim and assailant from misuse of data of seropositivity. The ethical considerations in testing victims of sexual abuse for HIV infection were reviewed by Fost.<sup>45</sup>

**Table 96.3:** Indications for HIV Testing and Possible PEP

Victims	Assailants
<ul style="list-style-type: none"> <li>Clinical profile consistent with AIDS</li> <li>Parent/victim insisting on test</li> <li>Anal rape, trauma genitally</li> </ul>	<ul style="list-style-type: none"> <li>High-risk behavioral profile</li> <li>HIV seropositive known or suspected</li> <li>Multiple assailants</li> </ul>

### GENITAL MYCOPLASMA INFECTIONS

The common agents are *Ureaplasma urealyticum*, *Mycoplasma hominis*, and *Mycoplasma genitalium*. Incubation periods are not completely elucidated yet, however, for *U. urealyticum*, it is about 14 days.

*U. urealyticum* and *M. hominis* are commonly isolated from the vagina of asymptomatic sexually active adult females. Colonization in adults by *U. urealyticum* has been shown to correlate with sexual activity.

*M. genitalium* has not yet been reported post sexual assault but has probably occurred as it is found in 10–20% of NSU in developed nations and has higher rates in some surveys in African countries.<sup>46</sup> Theoretically, antibiotic prophylaxis regimens commonly used post assault include cover for BV, chlamydia, gonorrhea, and *M. genitalium* (Azithromycin).

### HEPATITIS B VIRUS INFECTION

The incubation period for this double-stranded DNA virus varies from 40 to 110 days approximately.

Sexual transmission is a major route for transmission of hepatitis B in adults in western society.<sup>47,48</sup> Sexual assault, particularly anal penetrative sex, also with genital injury and/or bleeding increases the likelihood of transmission where the alleged offender is a carrier of hepatitis B virus, especially if 'e' antigen is positive. Hepatitis B vaccination should be considered in cases of adult sexual assault particularly in countries where increased incidence is likely, or in high-risk populations.

### HEPATITIS C VIRUS INFECTION

The incubation period for this enveloped RNA virus is similar to hepatitis B, 40–110 days approximately. Various studies indicate the rate of sexual transmission at about 5–10%,<sup>49</sup> but this has not been confirmed in some studies more recently.

It is not yet possible to evaluate the importance of hepatitis C in sexual assault. Screening for hepatitis C antibody and antigen may be performed if the alleged assailant is in a high-risk group for carriage of the virus, i.e., intravenous drug user. There is no vaccine available as yet and no method of prophylaxis.

## Sexually Transmitted Infections in Adult and Adolescent Victims of Sexual Assault

It is important to discuss the possibility of contracting STIs and prophylactic treatment recommendations with the patient and obtain consent for baseline and NAAT tests for chlamydia and/or gonorrhea, serology for hepatitis B, syphilis, and HIV.

The patient may already have STIs prior to the assault. Treatment based on specific diagnosis is more effective. Single-dose treatments at the time of initial examination are advantageous for sexual assault victims as compliance and follow-up with a multiple-dose regimen is often low.

For gonorrhea, a single-dose regimen effective against both gonorrhea and incubating syphilis should be preferred.<sup>50,51</sup>

Regimens including ciprofloxacin may be contraindicated in pregnancy and quinolone-resistant strains are common in Asia. Spectinomycin is safe in pregnancy but unreliable for throat carriage and not always available. All the regimens for gonorrhea should be followed by concomitant treatment for *Chlamydia* (*M. genitalium* cover as well preferably) and BV. Prophylactic antifungal anticandida treatment can also be offered.

## PROPHYLAXIS FOR STIs

In most cases of suspected child sexual abuse, prophylaxis is not indicated.<sup>51</sup> Prophylactic therapy is recommended when the child has had contact with an individual known to have a sexually transmitted infection, or has been sexually assaulted by a stranger and when the physician suspects the child will not return for follow-up, or if there are signs and symptoms but inadequate screening. Where there is a strong indication of abuse, but inadequate screening is carried out, consider prophylaxis.

Immediately after adult rape, prophylaxis should be aimed at ascending bacterial infection such as gonorrhea and chlamydia which can cause pelvic inflammatory disease within 48 hours. Rambow et al.<sup>52</sup> reiterate the need for prophylaxis as their study showed a follow-up rate of only 30%. However, for some, prophylactic treatment may act as a disincentive to return for the follow-up when tests will be more accurate. The CDC guidelines include cover for trichomonas and bacterial vaginosis.<sup>50</sup>

Patients often benefit psychologically from taking prophylaxis as this gives them a feeling of taking control over the risk of infection. Prophylaxis is not guaranteed for any of the viral STIs and especially in those with longer incubation periods. It may be offered, in very special circumstances, for HIV. Prophylaxis against HIV (PEP) requires specialist consultation.<sup>16</sup> Hepatitis B vaccination should be made available where indicated and can be started up to 14 days following sexual assault, the first of a three-dose hepatitis B vaccine course is given, hyperimmune gamma globulin is very rarely indicated. Education about long-term follow-up is mandatory.<sup>53</sup>

## FOLLOW-UP CARE

The importance of follow-up and a clearance STI screen cannot be over emphasized. The onus to arrange follow-up rests with the treating doctor, be it a general physician, sexual health physician, or pediatrician. Failure to do this may have serious consequences such as failure to ensure immunity to hepatitis B and pelvic infection to prevent future infertility, syphilis—secondary and tertiary disease, cervical dysplasia/neoplasia associated with HPV infection, HIV/AIDS, and reinfection from continual abuse.

Follow-up assessments also present the doctor with an opportunity to ensure that a child or young person is free of further abuse and that rehabilitative therapy is taking place. The timing of the follow-up should be rationalized and kept to a minimum by consideration of incubation periods, results from screening the offender, and potential consequences.

Although follow-up screening is essential for proper care, it is often missed because the victim fails to return.<sup>8</sup>

At the initial examination, the adult or adolescent patient needs to be instructed on possible symptoms of a sexually transmitted disease and urged to attend the STI Clinic for follow-up examination when diagnostic tests can be performed. The timing of follow-up screening will also depend on whether baseline screening was carried out and/or prophylaxis was given. The following time frames are suggested. At 2–4 weeks, examination and STI screening should be encouraged. At 3 months, syphilis serology, hepatitis B and HIV antibodies need to be done, where applicable.

If counseling is ongoing, the counsellor should reinforce the need for follow-up medical examination. On occasions medical treatment is indicated for post traumatic stress disorder. The presence of the same STI in victim and perpetrator has been useful in the court, i.e., sometimes in causing the perpetrator to change his plea.

Sexual abusers are often multiple offenders. Where a sexual offender is identified as a source of infection and she/he could have had access to other children in the family, all the children, if possible, should be screened. Where there is no disclosure by the child, screening adult members of a household has often identified carriers of infection. Informed consent is required for such screening (initial screening on urine specimens with NAATs may be very useful if large numbers are involved).

In the case of adolescent and adult victims of sexual abuse, contact tracing of the victim's own peer sexual partners as well as the abuser is important both to stop the victim becoming reinfected as well as to protect the partners.

### Summary

Sexual assault in adult and adolescent males and females has serious consequences affecting the physical, sexual, and mental health of the complainant. There is ample evidence for the cost effectiveness of dealing with acute and chronic post-traumatic stress disorder that commonly occurs. There is a high risk of psycho, socio, and sexual dysfunction that otherwise may follow, putting burdens on communities. For the individual assaulted, immediate medical care provided through sexual health clinics by practitioners trained in medico-legal medicine, with follow-up care also offered, is optimal. STI prophylaxis, PEP, and emergency contraception may be necessary in patients whether or not they are making a formal complaint. In resource-poor nations, in war zones, in countries with gender inequality, health budgets directed towards the assaulted may be pitiful at present. However, the WHO has acknowledged that violence including sexual violence needs to be addressed to help stop the spread of AIDS to many victims of assault, particularly wives and children.

## Sexual Health of Migrant Populations

Andy J. Williams • Beng T. Goh

### Introduction

In the 21st century, it is commonplace for individuals to move either temporarily or permanently between countries or within their own country as internal migrants or displaced persons. People may choose a permanent move for a wide variety of reasons such as relocating for a safe sanctuary from areas of conflict or persecution, education, work or in search of a different lifestyle. The number of people residing outside their country of birth is at an all-time high of over 200 million, more than double the number a generation ago.<sup>1</sup> Migrants are an enormously diverse population and fall into a number of different categories with different ethnicities, cultures, beliefs, and religions (Fig. 97.1). The majority of migrants will fall into a group named *economic migrants*. These are individuals and their families (mostly for reunification) leaving their country of birth to improve their quality of life and may include long-term migrants or short-term seasonal workers. *Frontier workers* are migrants who retain their usual country of residence but work in a neighboring state returning daily or weekly. *Refugees* are people with a fear of persecution for reasons of race, religion, nationality, membership of a particular social group or political opinion, who enter a country and claim asylum under the 1951 Geneva Convention. Once the fear has been proven to be well-founded, the claimant is granted refugee status. *Asylum seekers* are people who have fled to another country where they have applied for state protection by claiming refugee status, but have not received a final decision on their application. *Irregular or undocumented migrants* are people without legal status owing to illegal entry or the expiry of their visa. *Displaced persons* are people fleeing an armed conflict or escaping natural or man-made disasters or their effects. This term primarily covers persons displaced within the borders of their country of origin (i.e., internally displaced persons). A particularly vulnerable group of migrants are *trafficked individuals*. The trafficking of individuals is defined by the protocol against trafficking as “the recruitment, transportation, transfer, harboring or receipt of persons, by means of the threat or use of force or other forms of coercion, abduction, fraud, deception, abuse of

power or a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person, having control over another person, for the purpose of exploitation”.<sup>2</sup> A final significant contributor to the migrant population are the *international students*. They move to benefit from opportunities and academic programs offered by countries and educational institutions.

Many of these groups will have needs similar to their host country peers whereas others will have very different concerns and requirements including issues related to their sexual health.

Fig. 97.1: Bangladeshi migrants in London.

## Socioeconomic Issues

If socioeconomic issues are not addressed in the migrant population, their priority may just be to survive in a hostile environment rather than to look after their sexual health needs. In 2009, there were 36.5 million refugees under the care of The Office of the United Nations High Commissioner for Refugees (UNHCR) while the number of internally displaced persons in armed conflict situations was estimated at 27.1 million.<sup>3</sup> The degree of vulnerability in which migrants find themselves depends on a wide variety of factors, ranging from their legal status and government policies to their overall environment.

### IMMIGRATION CONCERNS

Laws that prevent migrants from accessing healthcare based on their immigration status are on the grounds of cost to taxpayers to fund their healthcare needs and that excluding them from social benefits would serve to deter future irregular/illegal migrants. Government policies may prevent internal migrants from one part of the country in accessing healthcare in another part. However, governments have legal obligations in relation to the health of every person within their jurisdiction under human rights legislation. National healthcare plans often discriminate against temporary migrants especially undocumented ones by making only emergency care available for noncitizens. Consequently, these migrants may initially self-medicate or consult quasi-medical practitioners within their community. Additionally irregular migrants may have concerns that health providers may have links to immigration authorities and that seeking care will highlight their illegal status. Migrant workers who have gone to considerable trouble to find work abroad, when diagnosed with a sexually transmitted infection in the host country may lead to their repatriation. As a consequence many migrant workers may prefer not to attend health services at all, further contributing to their vulnerability.<sup>4</sup> Professional confidentiality should be promoted and protected by the law, and support should be provided to health professionals in upholding this principle in the context of working with undocumented migrants.<sup>5,6</sup>

### INCLUSIVE SERVICES

In some countries, legislation has been implemented in favor of universal access to care and treatment of infectious diseases. For example, in the UK and Germany, infectious diseases are diagnosed and treated free of charge. However, in relation to other health problems such as mental health, where the benefit to the general public is not directly obvious, services are rarely available for irregular migrants.<sup>7</sup>

There are positive initiatives occurring among some large transnational corporations to ensure affordable and accessible healthcare for migrant workers and their families. Some of these companies realized the threat to productivity posed by poor health, especially HIV/AIDS and tuberculosis. In parts of southern Africa, for example, AIDS-related illness and death

has reduced the workforce by 20%.<sup>8</sup> Thus many corporations are collaborating with each other and with governments and civil society to tackle diseases such as HIV/AIDS.<sup>9</sup> The southern African mining industry, which depends almost entirely on migrant work forces, has taken a lead in this field.

In many parts of Africa migrant workers separated from their partners face a combination of poor housing, hazardous working conditions, and serious social disruption leading to alcohol abuse and patterns of sexual behavior that are conducive to the rapid spread of sexually transmitted infections, including HIV/AIDS.<sup>10</sup> In eastern China, migrants with partners were at a relatively low risk for engaging in casual sex.<sup>11</sup> In South Africa, migrant workers and their partners are twice as likely to be infected with HIV as nonmigrant couples.<sup>12</sup> In response to the negative health outcomes that result from isolating migrant workers, and in recognition of the right to family life, many corporations are altering their policies to allow for families to be together in an effort to enhance employee productivity.<sup>9</sup>

The right to health obliges governments to ensure that “health facilities, goods, and services are accessible to all ... without discrimination on any of the prohibited grounds”. In the context of health, these grounds are “race, color, sex, language, religion, political or other opinion, national or social origin, property, birth, physical or mental disability, health status (including HIV/AIDS), sexual orientation, civil, political, social or other status”.<sup>13</sup>

### WOMEN

Women migrant workers are a particularly vulnerable group who may work in unsafe and difficult conditions, encountering violence and abuse both at home and at work. Women are more likely to be trafficked into the sex industry in the host country. The problems faced by female migrant workers, particularly domestic workers, include “withholding of wages, acts of physical and sexual violence, under-nourishment and the seizure of passports”.<sup>14</sup> If found to be HIV positive they may be deported and, on returning to their countries of origin, may experience discrimination, social isolation, and difficulty in finding alternative work. Cases of HIV among domestic workers have been recorded in many migrant-sending countries such as Bangladesh, Indonesia, Philippines, and Sri Lanka and they represent a large percentage of those identified as living with HIV.<sup>15</sup>

### ACCESS AND COMMUNICATION DIFFICULTIES

Migrant workers may not even have the right to access healthcare in their country of work as with the internal migrants. In China, only 19% of rural-to-urban migrants had some form of health insurance and 26% were entitled to limited sick pay.<sup>16</sup> Where healthcare is available, migrant workers may find themselves unable to request time off from work to seek healthcare thus the location, distance, and timing of opening hours of health services may pose problems of access. A crucial element of the right to health is that all health services must be culturally appropriate.

However, these resources are usually limited and require user friendly staff to support and cooperate with migrants to prevent wrong diagnoses, inappropriate treatment, and poor compliance.<sup>17</sup>

Many migrants simply cannot communicate with health providers in a meaningful way. This is more evident in the field of sexual health where communication between the patient and the healthcare provider is of fundamental importance. As a result, the chances of misdiagnosis and inappropriate treatment have been and continue to be high. Only in a few countries are interpreters routinely used in healthcare facilities. Sweden has sought to alleviate this problem, especially in the area of mother and child health where adverse pregnancy outcomes in immigrant groups have proved to be as culturally influenced as they are biologically determined.<sup>18</sup>

## Sexual Health Issues

STIs are a major global cause of morbidity and mortality in migrant adults and children. STIs enhance the transmission of HIV and therefore adequate treatment of STIs is an important component of HIV prevention work worldwide. Antenatal screening for syphilis and HIV is important to prevent congenital syphilis and mother-to-child transmission of HIV.

Economic migrants are likely to be young adults moving alone to large urban centers seeking work. If denied of a stable relationship or family, their sexual needs may be catered for through other routes that may put them at increased risk of infection. Sex industry may develop to cater for their needs and any STI acquired may be transmitted to their partners while on home visits. Migrants have higher risk behavior for acquiring STIs. For instance, central and eastern European male migrants in London have higher rates of partner acquisition and paying for sex while both sexes reported more injecting drug use.<sup>19</sup> In Pakistan only 10% of migrant men reported condom use during the most recent contact with a sex worker.<sup>20</sup>

Migrants are likely to be in a position where they transfer an infection that is highly prevalent in their country of origin into their new host country or they may be moving from an area of low prevalence into an urban area, where the prevalence of STIs is higher. In China, a resurgence of syphilis in urban areas of economic development is driven by the migration of workers from rural areas, purchasing of sex and limited STI knowledge.<sup>21</sup> Furthermore, migrants may acquire STIs while in their host region or country and export them back to their region or country of origin on their return. For example, in Tanzania internal migrants were at a higher risk of HIV infection and contributed to increased rural HIV prevalence.<sup>22</sup>

Particularly vulnerable groups of migrants are the trafficked individuals and undocumented migrants.<sup>2</sup> These people may be moved to a country on the promise of a better life and the ability to send money home to their family. The reality may be a life of exploitation and forced commercial sex work. Their vulnerability and isolation is increased by their illegal status in their host country and consequently they are less likely to utilize formal healthcare services. Furthermore, health education campaigns

tend not to specifically target these groups. Trafficked individuals are more likely to have come from disadvantaged circumstances leading to increased cultural and language barriers and poor knowledge of behavior associated with risk of STIs. Healthcare workers should be aware of local resources available to these individuals and ensure that they are in receipt of ongoing care and support.

## Specific Sexual Health Issues Affecting Migrants

Migrants may import sexually transmitted infections such as HIV, syphilis, and hepatitis B and C infection from countries with a higher prevalence into their host country. Alternatively, they may acquire and transmit globally prevalent STIs such as Chlamydia, gonorrhea, genital warts, and genital herpes in their country of origin or in their host country. The management of these STIs should be identical in both migrants and nonmigrants with relevant investigations and treatment of the individual and their partners in appropriate settings. Other sexual health issues specifically affecting migrants include access to cervical screening programs, sexual assault, sexual dysfunction, and genital mutilation/cutting.

### HIV INFECTION

The HIV/AIDS epidemic appears to have stabilized. The annual number of new infections has fallen since the 1990s and the number of AIDS related deaths is declining due to the provision of antiretroviral medications. Sub-Saharan Africa still bears an inordinate share of the global HIV burden although HIV incidence is falling in 22 countries in the region<sup>23</sup> and this has a significant bearing on the incidence of HIV in their host country.

Immigrants living with HIV have become a strong feature of the epidemiology of HIV in several European countries and the path of migration seems to be influenced by former colonial ties.<sup>24</sup> It is therefore commonplace for people to move, for instance, from Uganda and Zimbabwe to the UK, from The Ivory Coast and The Republic of the Congo to France and from South Africa and Angola to the Netherlands. Sub-Saharan Africa bears 68% of the global HIV burden and therefore migrants from these countries may import HIV infection into their host country.<sup>25,26</sup> HIV risk may continue after migration as a result of sexual mixing patterns within the at risk communities or because of travel back to high incidence areas. Within Africa also migrant workers are a risk group for HIV infection.<sup>27</sup>

Data from UK in 2010 shows that 60% of the persons infected heterosexually were of black-African ethnicity and 70% acquired their infection abroad. Among those heterosexuals infected abroad, the majority have acquired their infection in sub-Saharan Africa. The number of heterosexually acquired HIV cases in people born in Asia, Latin America, and the Caribbean is also increasing reflecting both migration patterns and global HIV epidemiology. The number of deaths in black Afro-Caribbean individuals with HIV infection accounted for almost 30% of

all HIV related deaths; this may be related to late diagnosis or in some cases to not starting antiretroviral therapy at the appropriate time. Under diagnosis of HIV is more common among non-UK born people than among the UK born which raises questions about the adequate awareness of risk in non-UK born communities or a perceived stigma regarding testing and their onward entitlement to hospital services.<sup>28,29</sup>

HIV can be associated with stigma in many communities and this can be a barrier to seeking help which could delay diagnosis. Addressing stigma requires culturally appropriate approaches with the affected groups as well as education of the wider population. The general public needs to be reassured that they cannot acquire HIV through normal social contact with affected individuals. This will help to avoid the misconception that migrants pose a health threat to the general population which can lead to prejudice that is likely to hinder overall HIV control.

## SYPHILIS

Syphilis is an entirely treatable sexually transmitted infection but with an estimated 12 million people infected each year it remains a global problem.<sup>30</sup> Expectant mothers infected with syphilis can transmit the infection to their unborn child and despite national policies on antenatal testing more than 1 million infants are born with congenital syphilis each year.<sup>31</sup> China is experiencing a resurgence of acquired and congenital syphilis, especially in their migrating population.<sup>32,33</sup> Similarly it has been shown that male migrants returning to Nepal from Mumbai have high rates of syphilis infection after engaging in pre- or extra marital sex, sex with multiple partners including sex workers.<sup>34</sup> Outbreaks of syphilis in central and eastern Europe and Russia were reflected in women and female sex workers from these countries living or working in their host countries in western Europe.<sup>35–37</sup>

Part of the difficulty experienced with syphilis screening and testing is that traditional serological testing relies on availability and the patients returning for their results, which can be a problem for migrants in particular. The development of a new robust rapid specific test provides an opportunity to scale up syphilis screening in many settings.<sup>38</sup>

## HEPATITIS B AND HEPATITIS C INFECTION

Viral hepatitis B and C are a major health problem worldwide. Migration of individuals with chronic viral hepatitis infection substantially contributes to the prevalence of these infections in low-endemic countries.<sup>39–43</sup>

Both chronic hepatitis B and hepatitis C can cause cirrhosis and hepatocellular carcinoma (HCC). The epidemiology of HCC is therefore changing as a result of migration and host countries of individuals from highly endemic areas are observing increases in their incidence of HCC.<sup>44</sup> Many of the migrants with chronic hepatitis B infection will have acquired their infection at an early age, hence hepatitis B vaccination policies will be unable to protect the already infected migrants from the sequelae of hepatitis B infection. For this group diagnosis and treatment may, however,

contribute to reducing the impact of the infection on their individual health, and awareness of the disease can prevent transmission to others, particularly transmission to babies from their mothers. Treatment for chronic hepatitis B has improved and new drugs for the treatment of hepatitis C are on the horizon. Efforts should therefore be made to identify individuals in order that treatment can be offered preventing long term complications. Screening programs targeting migrants from endemic countries that could be implemented are population based screening, opportunistic testing, or enhanced contact tracing.<sup>45</sup> Universal hepatitis B vaccination as recommended by the WHO in all infant vaccination programs worldwide<sup>46</sup> is essential to prevent transmission in the uninfected and the population at large as targeted vaccination programs to high risk groups are not effective.<sup>47</sup> Failure to implement universal vaccination affects migrants from hepatitis B endemic area and their family and sexual partners disproportionately. In rural Vietnam, out-migration of the husband was associated with an increased risk of hepatitis B surface antigen seropositivity among married women.<sup>48</sup>

## CERVICAL CANCER AND SCREENING PROGRAMS

Access to a cervical cancer screening test to prevent cervical cancer should be available to all.<sup>49</sup> Geographic variations in the risk of developing cervical cancer are associated with variation in the occurrence rate of oncogenic human papillomavirus (HPV) around the world, smoking rates, sexual habits, and the availability of screening tests.<sup>50</sup> The variability in the cervical cancer rates between the migrant women depends on their country of origin and the variability of the above stated risk factors. Increased rates have been observed in women migrating from Poland and Bosnia,<sup>51</sup> Norway, Denmark and Central America<sup>50</sup> and internal Spanish migrants.<sup>52</sup> Lower rates of cervical cancer have been observed in women originally from Iran, Iraq, and Finland<sup>51</sup> and southern Asia and east Africa.<sup>50</sup> Evidence from Canada, Australia, and New Zealand reinforces lower uptake of cervical cancer screening among migrant women compared with their native counterparts.<sup>53–55</sup> Increasing age at the point of migration has also been noted as a risk factor for cervical cancer.<sup>50</sup> It is important to understand the disparities in healthcare suffered by migrant women compared with nonmigrants.<sup>56</sup> Culturally sensitive cancer prevention programs should focus on individual risk patterns and high risk women, especially older women who have recently migrated, should be targeted.

## SEXUAL DYSFUNCTION

Sexual dysfunction is a common complaint in both male and female migrants attending sexual health clinics. Premature ejaculation is more common in migrants from the Indian subcontinent particularly Islamic men.<sup>57</sup> Factors associated with premature (rapid) ejaculation in men included: anxious first sexual experience (associated with a fear of being discovered and wanting to finish early), sex before marriage, sex outside of marriage, religion,

“stress,” and exposure to Western images. These factors have useful therapeutic implications when counseling men with premature ejaculation but may also be reflective of sexual dysfunction with alternative presentations. Treatment of premature ejaculation using masturbatory techniques may not be acceptable to many migrants with strong cultural and religious beliefs and so other methods of treatment may be required. When discussing sexual dysfunction it is important to understand cultural relativism and that the healthcare provider’s view of “normal” sexual behavior is perhaps not the same as that of their patient.<sup>58–61</sup>

## **RAPE/SEXUAL ASSAULT**

Rape has been a common feature of many armed conflicts around the world. Women in such circumstances may be internally displaced or choose to migrate, seeking asylum abroad. Aside from the physical and psychological distress felt by the individual, women are often rejected by their family or community because of the shame rape brings. Sexually assaulted women are also at risk of acquiring STIs including HIV. The war in former Yugoslavia increased all forms of violence against women including domestic violence, particularly in inter-ethnic marriages, death threats against women, rape and threats with weapons. In Rwanda, there were reports of women being gang-raped and sexually mutilated; fathers forced to rape their daughters; and sons their mothers.<sup>62</sup> The UN Security Council specifically included sexual violence against women as a weapon of war.<sup>63</sup>

Rape victims who are displaced or are seeking refuge in another country will therefore need health services to be aware of the problem and will need culturally appropriate psychological and physical support. As a minimum, good practice will ensure that women are offered a suitable appointment with a minimal waiting time and private waiting area for use if the patient is distressed. An independent translator should be provided and onward links with the relevant and other support agencies ensured.

## **FEMALE GENITAL MUTILATION OR CUTTING**

Female genital mutilation (FGM) refers to all procedures involving partial or total removal of the external female genitalia, or other injury to the female genital organs for nonmedical reasons. The term ‘female genital cutting’ reflects the use of a nonjudgemental terminology with practising communities. In African countries, more than 90 million girls and women over the age of 10 years are estimated to have undergone FGM, and some 3 million girls are at risk of undergoing the procedure each year. The practice of FGM has been reported from all parts of the world, but it is most prevalent in 28 countries in Africa and some countries in Asia and the Middle East. As a result of international migration, the practice of FGM and its harmful consequences is a concern for a growing number of women and girls in Europe, North America, Australia, and New Zealand.<sup>64</sup>

This practice is a violation of girls’ and women’s human rights and is illegal in many areas of the world. FGM is known to be harmful in many ways as it involves the removal of healthy genital

tissue, interferes with the natural functioning of the body, and causes several immediate and long-term physical, psychological, and sexual consequences. Despite there being evidence to support the occurrence of primary infertility after genital mutilation, families and individuals continue to perform it because they believe that their community expects them to do so. They suspect that if they do not respect the social rule, they will suffer social consequences such as derision, marginalization, and loss of status.<sup>65</sup>

## **Vulnerable Groups**

Aside from a higher rate of infections within certain populations, migrants may face compounding factors on arrival in their host country which further increase their risk for acquiring STIs/HIV.

## **DRUG AND ALCOHOL USERS**

Recreational drug use is associated with increased sexual risk taking and intravenous drug users are more at risk from blood borne virus infections. After a period of drug control in China there is evidence of an increase in illicit drug use in internal male migrants. Depression and earning a higher income were positively associated with drug use.<sup>66</sup> Drug users who move country may find themselves further marginalized due to language barriers and difficulty with access to healthcare. Italian intravenous drug users living in Amsterdam reported a high prevalence of needle borrowing, needle lending, and HIV infection.<sup>67</sup> A pan-European survey of undocumented migrants carried out by Médecins du Monde revealed that the prevalence of drug abuse in this group and in the under-25s population was approximately 5% and 9%, respectively. Prevalences varied by country with nearly 20% prevalence in Italy.<sup>68</sup> Among male Hispanic/Latino migrant farm workers in Southeast USA, 40% who reported sex during the past 3 months performed it under the influence of alcohol.<sup>69</sup> Outreach work is needed with this population to educate them regarding risk reduction and so decrease onward transmission of infections. Close links with local substance misuse services are beneficial.

## **COMMERCIAL SEX WORKERS**

In many countries in Europe, the majority of sex working population is made up of foreigners. In countries where commercial sex is legalized and commercial sex workers (CSWs) have been registered, unregistered sex workers, many of whom will be migrants, may even outnumber the registered CSWs.<sup>70</sup>

Sex workers from eastern Europe working in western European countries had a higher prevalence of syphilis and little knowledge of STD risks or effective contraceptive use.<sup>32</sup> Street based sex workers in East London showed high rates of drug use (92%), a high prevalence of syphilis (58%) and that 28% of them were non-UK born.<sup>71</sup> Work with internal economic migrant female sex workers from China on their barriers to condom use and subsequent HIV risk showed that their use of condoms was influenced by gender norms, familiarity, and whether more money was offered.<sup>72</sup>

In a population of migrant sex workers in Spain, 5.2% had antibodies to HIV-1, 3.5% tested positive for HBsAg, and 3% were positive for syphilis antibodies. However 28.6% of Ecuadorians had active syphilis and all HIV-1 positive in this group were transsexual men.<sup>73</sup>

Female sex workers in the US Virgin Islands using illicit drugs were significantly more likely to report unprotected sexual activity, client violence, and sexually transmitted infections. This group of women also engaged in sex work in a significantly greater number of countries and were more likely to work in locations outside the US Virgin Islands.<sup>74</sup>

Targeted work is needed with this cohort to ensure the availability of sex education regarding infection prevention and contraception. Services should have links to drug-dependency units and have facilities to support women, should they choose to continue working in the sex industry or not. Clients also need to be educated on safer sex. For instance, a behavioral survey of migrant taxi drivers in Bangladesh showed that 64% of the sample reported sex with multiple commercial sex partners and only 5.6% used condoms consistently. It indicates that not only CSWs but also migrant men who are likely to be their clients need to be a target for intervention.<sup>75</sup>

### MEN WHO HAVE SEX WITH MEN (MSM)

A further vulnerable group are the black and minority ethnic (BME) men who have sex with men (MSM) population. MSM migrants from the Caribbean, Africa, South Asia (India, Pakistan, Bangladesh, or Sri Lanka) and China/South-East Asia (Malaysia, Thailand, Philippines) and Japan have been shown to be more likely to report unprotected anal intercourse with casual male partners and also likely to report female sexual partners.<sup>76</sup> Seventy-two percent of young migrant MSM in Beijing, China had never had an HIV test. Barriers to testing included perceived low risk of HIV infection, stigmatization, inconvenience of testing, and lack of confidentiality while HIV testing behavior was associated with increased high risk sexual behavior and a history of sexually transmitted infections.<sup>77</sup> In the United States, BME MSM bear a disproportionate burden of incident HIV; among young BME MSM surveyed in 6 US cities between 1994 and 2000, the HIV incidence was 14.7% compared to 2.5% among white MSM.<sup>78</sup> High rates of bacterial STIs and risky sexual behaviors among black minority ethnic groups, compounded by racism and cultural taboos surrounding sexual orientation, mean that we must remain alert to the sexual health needs and evolving epidemiology of HIV among BME MSM. Furthermore, BME MSM may be marginalized by the BME community and by the MSM community and therefore appropriate and culturally specific sexual health services should be planned.<sup>79,80</sup>

### Actions Required

International and Governmental bodies and agencies need to work together to ensure that migrants have proper safeguard, protection, and provision of appropriate health services.

Many health systems are based on Western medical knowledge and practices. Health policies assume that migrants will adopt the health practices and beliefs of the host society. However, the access and the use of health services can be obstructed by differences in health beliefs and knowledge. National health services need to invest in overcoming the language barrier and training health service providers to identify migrants at risk of STIs and HIV and ensure acceptability of their service to these individuals. Health service providers need to be informed about the cultural background and particular barriers that different types of migrants in different situations may face. Migrants' participation in health service provision will improve the accessibility of these services for migrant communities. The understanding of different medical traditions will enhance the cultural appropriateness of health and social services.

Migrants should be provided with information on the health services that are available for their use. Outreach work can facilitate and integrate targeted STI prevention measures into education programs. Often migrants are neither included in the development of migrant services nor asked for feedback on these services. Thus, many services are not used because they are not culturally acceptable to migrants. A study in Switzerland has shown that female migrants' lack of awareness of healthcare and preventative services has been a major reason why they have been underutilized.<sup>81</sup> They identified a need for culturally and linguistically appropriate education on contraception, family planning, and cancer screening. Lessons can be learnt from the Swedes who, in their National Action Plan for STI/HIV prevention, suggest that targeted information about STIs and HIV should be provided to persons recently arriving in Sweden.<sup>82</sup> An important strategy in reducing the spread of HIV is to look at measures to integrate new Swedes into their society. Therefore, efforts should be made to counteract discrimination, xenophobia, and racialism to improve society's attitudes to minority groups, particularly homosexuals and migrants from Africa and Asia. The fact that many of the groups targeted for information about HIV and AIDS have experienced discrimination in their country of origin instinctively increases their reluctance to accept messages from the host society.

### Conclusion

Migrants are an extremely heterogeneous group and coping with cultural, social, and psychological effects of migration is a very difficult and prolonged adaptation process. The management of migrants' sexual health goes beyond the traditional management of diseases among mobile populations and is intrinsically linked with the broader social-determinants of health and unequal distribution of healthcare and social services. It is therefore paramount that different disciplines work in close partnership to avoid social exclusion and improve the health of all people including migrants. Therefore, work on facilitating social and economic integration of migrants is vital. If we can promote a greater understanding of the needs of the migrants and encourage a charitable attitude among the indigenous population of their

host country we will ensure that helping migrants does not undermine helping the locally underprivileged. Integrating migrants into society can enrich their host country both culturally and economically.

### Summary

- Migrants are a heterogeneous group with different needs.
- Sexual healthcare should be provided to migrants regardless of their legal status.
- Healthcare services should be culturally appropriate with access to interpreters.
- Specific infections prevalent in the individual's country of origin must be considered.
- Some knowledge about their sexual practices, cultural values, traditions, and taboos will be helpful.
- Particularly vulnerable groups of migrants should be identified for targeted STI prevention work.
- Efforts need to be made to counteract discrimination of migrants and to integrate them into their host society.

## Introduction

In everyday life, the word “sex” is often used to mean male or female (biological gender) or to refer to physical activity involving the genitals (having sex). The word “sexuality” has a broader meaning. Sexuality means a dimension of personality instead of referring to a person’s capacity for erotic response alone.<sup>1</sup> Human sexuality is defined as that aspect of the human condition, which is manifested as sexual desire, appetite, associated physiological response patterns, and behavior which leads to orgasm, or at least pleasurable arousal, often between two people, but not infrequently by an individual alone.<sup>2</sup>

It will be scientific to use the word “sexuality” as it is holistic and refers to the person as a whole including his/her thoughts, experiences, learnings, values by virtue of being male or a female.<sup>3</sup>

## Human Sexual Response Cycle and Sexual Dysfunctions

Consequent to direct observation of 10,000 live sexual cycles, it was in 1966, Masters and Johnson first described the four stage model of the normal human response cycle, in their classic book, “Human Sexual Response.”<sup>4</sup> Human sexual response cycle consists of: Excitement Phase, Plateau Phase, Orgasm and Resolution Phase. Kaplan added “Sexual Desire” to the classical four stage model.<sup>5</sup> Subsequently, in 1970, the famous couple, Masters and Johnson used the term “sexual dysfunction”<sup>6</sup> principally intending to convey psychological malfunctioning; at that time most sexual dysfunctions were considered psychogenic. Based on the ideas of Masters and Johnson and Kaplan, in 1980, the concept of “Psychosexual Dysfunction” appeared in the third edition of Diagnostic and Statistical Manual of Mental Disorders (DSM) of American Psychiatric Association.<sup>7</sup> The current DSM-IV classification (American Psychiatric Association 2000) defines sexual dysfunction as characterized by disturbance in sexual desire and in the psycho-physiological changes that characterize the sexual response cycle, causing marked distress and interpersonal difficulty.<sup>8</sup> Following are the definitions given in DSM-IV (Text revised):

### 1) Sexual desire disorders

- **Hypoactive sexual desire disorder (HSDD):** Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person’s life.
- **Sexual aversion disorder:** Persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner.

### 2) Sexual arousal disorders

- **Male erectile disorder (erectile dysfunction [ED], impotence):** Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection.
- **Female sexual arousal disorder (FSAD):** Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement.

### 3) Orgasmic disorders

- **Premature ejaculation (only in men):** Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity. (This definition is not universally accepted; some definitions include a specific time limit of one or two minutes between vaginal penetration and ejaculation.)
- **Male orgasmic disorder:** Persistent or recurrent delay in, or absence of orgasm following a normal sexual excitement phase. The clinicians should take into account the patient’s age and whether the stimulation is adequate in focus, intensity, and duration.
- **Female orgasmic disorder:** Persistent or recurrent delay in, or absence of, orgasm following a normal sexual

excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of female orgasmic disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.

#### 4) Sexual pain disorders

- **Dyspareunia (both in men and women):** Recurrent or persistent genital pain associated with sexual intercourse in either a male or a female.
- **Vaginismus (only in women):** Recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse.

According to DSM-IV, to be defined as a "dysfunction" these disorders must also cause marked distress or interpersonal difficulty, and not just exclusive presence of the general medical condition.

#### PERSISTENT GENITAL AROUSAL DISORDER (PGAD)

This is a rare condition and was first reported recently by Leiblum & Nathan.<sup>9</sup> Almost all reported cases have been in women. It can be identified by the following descriptive features:

Genital and breast vasocongestion persisting for hours or days, which resolves only temporarily following orgasm and may require multiple orgasms to get relief. The feeling of genital response, is not associated with any sense of sexual desire or excitement, is intrusive and disturbing and can be triggered by a variety of non-sexual stimuli. No consistent cause has been identified for this condition. Even though several hypotheses are proposed, none had been proved. There is also lack of evidence-based data regarding the prevalence of PGAD and the condition is not mentioned in DSM-IV.

#### Epidemiology of Sexual Dysfunctions

**Erectile dysfunction:** In the recent years, many studies on prevalence of erectile dysfunction have been published, but the conclusions vary significantly. A review of 15 large scale prevalence studies from 1994 to 2004, reporting men with erectile dysfunction as a percent of the studied population shows that the prevalence of ED varied from a low of 10.2% in Laumann's US study of men aged between 18 and 59 years, to a high of 64% in Akkus' Turkish study of men over 40.<sup>10–17</sup> The most popular Massachusetts male aging study demonstrated an overall prevalence of 52% in men aged 40–70.<sup>11</sup>

**Premature ejaculation (PME)** is one of the most common male sexual dysfunctions, affecting 5–40% of sexually active men.<sup>18</sup> It is believed that there is a higher frequency of PME in adolescents or young adults. PME is most frequently reported by men in East Asia and less frequently by men in Middle Eastern and African countries. The European prevalence of PME is said to be between that of East Asia and Middle East and African countries.<sup>19</sup>

A recent European survey of 2467 women in France, UK, Germany, and Italy indicates that the percentage of women with low sexual desire is 16% in the age cohort from 20 to 49; 29% in the same age cohort in women who experienced surgical menopause; 42% in postmenopausal women aged 50–70 with natural menopause and 46% in the same age cohort after surgical menopause.<sup>20</sup>

**Sexual aversion disorder in women** is frequently a component of other diagnostic disorders, especially anxiety-based disorders.<sup>10</sup> In a study done by Hutchings and Dutton, it had been concluded that 75% of sexually abused women had anxiety disorders as compared to 21% of non-abused women with anxiety disorders.<sup>21</sup> Another study by Dinwiddie et al.<sup>22</sup> demonstrated the increased incidence rates of psychopathologies in those twins who were sexually abused as compared to those twins who were not abused. This shows a strong correlation between childhood trauma or sexual abuse and incidence of panic disorders.<sup>22–24</sup> This hypothesis was initially linked to sexual aversion disorder by Kaplan<sup>25</sup> in her discussion on clinical perspectives of intimacy and panic disorders.

The epidemiological data on **female sexual arousal disorder (FSAD)** show a wide range of prevalence, based on the study methods adopted and the definitions used in the study. The overall prevalence rates are between 6% and 49%<sup>13,26–32</sup>. Two studies concluded that the prevalence of FSAD is increasing with increasing age, peaking after the age of 50 years.<sup>30,31</sup>

#### Sexually Transmitted Infections and Sexuality

It is a depressing reality that one can get a disease from making love. And yet, STIs are a very real concern. Probably STIs are the most prevalent infectious diseases next to the common cold; hence, the need for a discussion on sexuality in a textbook on STIs.

It is important to keep one distinction in mind. One does not get an STI because he/she has sex. Rather, one contracts an STI through sexual contact with an infected person. For suppression of sexual activity, moralists have long used the idea that an STI is one of the penalties of sex. It is an old and tenacious fallacy. STIs occur as a result of ignorance and lack of sexual responsibility. It is the consequence of failure to plan sexual activities and to take responsibility for sexual behaviors.<sup>32</sup> Sexual abstinence as a preventive means against STIs is not the answer. The answer is to be aware of preventing, detecting, and treating STIs so that they do not interfere with a person's life and sexual functioning.

It is important to realize that the sexual urges and practices of human beings are unlikely to be inhibited by the threat of severe pain, complete disability and even death, including the morbidity which may result from sexually transmitted infections. If it was so, STIs would have been eradicated long ago. In spite of the AIDS scare, extramarital sex has not disappeared.<sup>33</sup>

Because of this recent epidemic of AIDS, interest in human sexual behavior and the factors influencing it has acquired enormous significance.

## FACTORS INFLUENCING SEXUAL BEHAVIOR

As with virtually all aspects of human behavior, there are elaborate laws and codes of morality, both written and unwritten, which govern sexual relations/acts/behaviors. It is unfortunate that many of these are based on taboos and superstitions, and above all ignorance.<sup>34</sup>

It may be surmised that when human beings were evolving, their survival was by no means certain, and thus a very high reproductive rate was a great advantage. It seems possible that many elaborate cultural and social patterns which have evolved around the act of sex are a result of that original basic biological need to procreate as much as possible.<sup>34</sup>

Today humans are no longer in danger of under reproducing but rather over reproducing. Consequently, the primary focus of human sexuality, namely procreation, is being replaced with other foci of sexuality like recreation and relation. Naturally these new needs will have to be governed by a new set of moral codes. Unfortunately while moral codes are rapidly changing, superstitions and ignorance are not changing. They continue to cling tenaciously in the minds of not only the non-medical persons but also the medical fraternity.

The belief that humans indulge in sex only for the sake of sexual pleasure is no more tenable. Sorenson<sup>35</sup> had identified a variety of reasons other than sexual pleasure, which make people to be sexually active. Any healthcare professional has to necessarily understand all these in order to be able to manage people who come to him/her with sexual problems and problematic sexual behavior.

Human beings may be described as learning animals. However, unlike other animals human beings are sexually excited by different kinds of sexual stimulation and circumstances. This excitatory process is largely learned, and the various types of responses to individual stimuli and situations depend on the individual's past experience.

These learning procedures may be, and often are, purely trial and error, but by far the greater part are learned from other people and within the general social context in which the individual is brought up and lives. Thus, in addition to being learning animals, humans are also social animals. As a result their sexual behavior is inevitably channeled into certain patterns consistent with their particular cultural backgrounds. From this evolving culture the individual will learn right from wrong, various codes of conduct, and how, when, and where to behave in certain ways. These codes and behaviors may, of course, be quite different for men and women, and even between social strata within the same society. But whatever the differences, every individual will be subject to strong pressures to conform to the traditional sexual behavior patterns accumulated through hundreds, and perhaps thousands, of years of cultural heritage.

Human sexual behavior then, must be viewed with these three things in mind; the purely biological factors, the learning processes, and the sociocultural environment. Since large cultural variations exist between different groups of

people throughout the world, it is not surprising to find, as anthropologists have amply demonstrated, large variations in sexual behavior in various civilizations all over the world.

## PREMARITAL SEX

Ford and Beach<sup>36</sup> divided societies into three types, while reviewing the sexual behaviors:

1. Restrictive societies in which sexuality outside marriage was generally discouraged.
2. Semi-restrictive societies with formal prohibitions but not enforced with any vigor. Sexual behavior among the unmarried was accepted provided it was in secret, but if pregnancy ensued, marriage was expected.
3. Permissive societies; in some cases the permissiveness applied to early childhood only, but often continued at least until marriage. Sexual activity between young people was expected, but once again, the occurrence of pregnancy was seen as an indication for marriage.

Broude and Greene<sup>37</sup> in human relations area file (HRAF) reported that premarital sexual activity is not common for females in 43% and for males in 31% of the 141 societies they studied. Whyte<sup>38</sup> felt that a double standard exists for premarital sexuality in 44% of the societies surveyed.

## SOURCES OF INFORMATION

There are three important sources of information: (i) historical evidence of changing patterns of sexual behavior; (ii) cross-cultural anthropological studies of primitive societies; and (iii) surveys of sexual behavior and attitudes in modern societies.

It is important to recognize that none of these sources are foolproof and are as susceptible to bias as any other source of information. However, it must be acknowledged that these sources are valuable in the sense that they are indicators or guidelines of sexual behavior of large ethnic groups.

While anthropological data are a rich source, few anthropological studies have focused on sexuality.<sup>39–41</sup> Since the past 50 years more than 50 surveys on the sexual behavioral patterns of the western society have been conducted. Unfortunately their value is very variable. Standing out from others in terms of size and importance are the Kinsey reports.<sup>42–44</sup>

While some surveys concentrated on the behavior alone, others concentrated on attitudes in addition.

In spite of the difficulties in obtaining representative population samples, there is much to be gained by surveying sexual behavior. They are useful in: (i) establishing norms for comparative purposes, (ii) policy making in education and health, (iii) challenging false myths, (iv) changing social attitudes, and (v) testing hypotheses about relationships between sexuality and other variables.<sup>45</sup>

## SEXUAL NORMALITY

A tendency in medical writing on sexuality is to regard certain forms of sexual behavior as either normal or pathological. This categorization makes the medical personnel difficult to understand the concerns of an individual who seeks medical help, e.g., homosexuals. While some of the so-called “pathological” individuals may seek help, others may not, even though they can be (mistakenly) considered to be “pathological.” These individuals do not seek help to “cure” their condition.

Attitudes to sexual behavior are so very emotive and hence any behavior that is not regarded as normal will tend to be seen as abnormal in a derogatory way.

There are many concerns regarding sexuality. Perhaps the biggest and most vexing of all is: “Am I normal?” Almost every human being has this doubt at some point in his/her life, in relation to sexual development, sexual practices, feelings, and desires. Unfortunately, there are no definitive answers to these bothersome questions. The most appropriate answer will be “it depends.” It depends upon the context in the individual’s life. So, how is one to assess normality? Wardell Pomeroy<sup>46</sup> was of the opinion that there are multiple standards to assess normality: statistical, religious/moral, and psychological/sociological.

From a sociological perspective behavior that falls outside the accepted customs and rules of a particular society is deviant. The psychological perspective stresses that anything that produces a subjective sense of distress is abnormal. Statistically, normality becomes a matter of numbers. If a particular type of sexual behavior is frowned upon by a significant segment of the population, then it becomes abnormal. Similarly what is frowned upon by a significant religious group is abnormal. Michael Carrera<sup>47</sup> adds two more standards, namely, legal and phylogenetic. The legal perspective is that anything which violates the law is abnormal. The phylogenetic (biological) viewpoint of normality implies healthy against diseased. While each standard appears to be definitive from its perspective, they all have their own exceptions. To conclude, no one standard is comprehensive. Sexual behavior is culturally and religiously relative. Standards of sexual behavior vary with time and place. Scientific research, by giving us clearer view of what actually happens can alter our views.

The best and most realistic criteria for judging if a particular sexual practice is acceptable or not is whether it is harmful in some way to either oneself or the partner. It is indisputable that one cannot do oneself good by harming others. STIs greatly enlarge the possibility of harming others through sex or being harmed by them. However, the ethics governing our attitudes towards STIs need not be different from ethics of sexuality in general. Behavior that is based on awareness, caring, compassion, and responsibility will serve well.

## CONCEPT OF SEXUAL DEVIANCE

Deviance is a behavior that contravenes the norms of society. These norms combine the institutionalized norms or laws and the internalized and shared norms or mores. Deviance is sometimes

defined in terms of statistical abnormality or of psychopathology. The statistical criterion tells us nothing of the value or the problems associated with a particular form of behavior. The criteria used to define psychopathology may be no more than medical rationalization of the social criteria. A typical example of this is homosexuality. The sociological definition is however valid and important as it confronts us with the social stigma, which plays such important negative role in the lives of “deviant” individuals. Unfortunately, the term deviant has grown to have pejorative connotations, so that when using it one may be accused of expressing a negative value about the particular behavior or individual. This is unfortunate as the concept of deviance is essential to our proper understanding of the plight of these individuals in society.

Gagon et al.<sup>48</sup> drew an important distinction between three types of sexual deviance. The first they called “normal deviance,” this encompasses behaviors such as masturbation, premarital sex, and oral-genital sex. These activities are frowned upon in some parts of the world even today and are legally proscribed. These behaviors, nevertheless carried out by large number of people, are becoming progressively destigmatized. The other two types of deviance distinguish between behaviors which are associated with particular subcultures (such as homosexual subcultures) called subcultural deviances and those which are not (such as exhibitionism or incest). The later group is known as “individual deviance.” The existence of a sub-culture with which the deviant individual can identify may be crucial to his wellbeing and adaptation. This helps the concerned individual to have a social group in which he feels normal. Otherwise he will always feel abnormal and stigmatized. Such sub-cultures are never static. They are constantly evolving and changing, reflecting the changing attitudes of the societies. In the mid 19th century, homosexuals had no homosexual subculture. Now there is an international network of such organizations. All homosexuals may not identify with these groups and may remain isolated. But the option is there now. Other types of “deviant” sexuality have generated their own organizations or sub-cultures. There are now well-established organizations of transvestites and trans-sexuals, and to a lesser extent of fetishists and sadomasochists.

## LABELING AND STIGMATIZATION

Using words like “normal” or “abnormal” to describe behavioral patterns may sound scientific or official. This is called “labeling.”<sup>49</sup> Labels affect how an individual views others and in turn how others view the individual.

The negative effects produced by labeling are known as “stigmatization.” It brands people as undesirable with social, legal, and economic consequences. In order to avoid the stigmatization caused by labeling, the word “paraphilia” has been suggested to refer to those behaviors which were known as “perversions” or “deviations.”

## Paraphilias

The word paraphilia is from Greek roots “para” and “philia” meaning “altered” and “love.” Currently, they are classified as

psychiatric disorders. In the third revised edition of diagnostic and statistical manual (DSM-III) of the American Psychiatric Association<sup>50</sup> the legal term perversion was dropped and the biomedical term paraphilia was adopted.

By far the most comprehensive definition of paraphilia is given by Money.<sup>51</sup> He defines paraphilia as “a condition occurring in men and women of being compulsively responsive to, and for optimal initiation and maintenance of sexuorotic arousal and the facilitation or attainment of orgasm, obligatively fixated and dependent on an unusual, personally or socially unacceptable stimulus either perceived directly, or in the imagery or ideation of fantasy.”

A paraphilia can revolve around a particular sexual object (e.g., children, animals, underwear) or a particular sexual act (e.g. inflicting pain, making obscene phone calls).<sup>49</sup>

Money<sup>52</sup> described fifty-two types of paraphilic sexual behaviors ranging from “acrotomophilia” (amputee partner) to “zoophilia” (sex with animals).

Most paraphilias involve sexual acts that violate the law in one form or another. For example, exhibitionism comes under laws against “indecent exposure.” Voyeurism falls under “an unwanted invasion of privacy.” Sadistic acts may violate laws on assault.

Hence, paraphilics are in a state of limbo in a legal sense. Often paraphilics are categorized as “sexual psychopaths,” a term that is not a psychiatric diagnosis but a legal label. This designation permits the society to impose an indeterminate punishment and also to dub them as a menace to society. While this may be true of some paraphilics, it is difficult to see how someone like a transvestite is a menace or danger to the society.

The issue being so, how to determine which paraphilias are pathological and which are not, at least in a legal sense. The laws of many countries declare by fiat which paraphilia, if enacted, are criminal offences. Such paraphilias were called “crime against nature” because they break what was assumed to be God’s natural law. In these instances, the natural law is specified as “God’s natural law of procreation.” In recent times, however, some law agencies are handing over these “crimes against nature” to medical fraternity, so that they can be reclassified as illnesses instead of crimes.

Money distinguishes between benign acts that do not harm others and pathological acts, which harms others by utilizing the concept of mutual consent.<sup>53</sup>

As of today there is no general agreement on the etiology of paraphilias. A variety of factors have been postulated to cause paraphilias. These can be broadly classified into biological, cognitive behavioral, and psychodynamic. Prenatal developmental anomalies,<sup>54</sup> increased testosterone levels,<sup>54</sup> organic brain disorders,<sup>55</sup> obsessive-compulsive disorders<sup>56</sup> are among the cited biological factors. Behavior therapists suggest that paraphilias begin via a process of conditioning.<sup>57</sup> Psychoanalytic theory is that these conditions represent “a regression to or a fixation at an earlier level of psychosexual development resulting in a repetitive pattern of sexual behavior that is not mature in its application and expression.”<sup>58</sup> Money proposed the “vandalized love map” theory to explain paraphilic behavior.<sup>59</sup>

The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR), the prevailing resource for diagnostic criteria of paraphilias, describes the essential feature of paraphilias as recurrent, intense, sexual urges, and sexually arousing fantasies generally involving non-human objects, the suffering or humiliation of oneself or partner, or children or other non-consenting persons.<sup>8</sup> The DSM-IV-TR lists the following paraphilias: exhibitionism, fetishism, frotteurism, pedophilia, sexual masochism, sexual sadism, transvestic fetishism, voyeurism, paraphilias NOS (not otherwise specified).

### **Exhibitionism**

Exhibitionism is the exposure of genitals to a non-consenting stranger. In some cases, the individual may also engage in autoeroticism while exposing himself. Generally, no additional contact with the observer is sought; the individual is stimulated sexually by gaining the attention of and startling the observer.

### **Fetishism**

People with this disorder achieve sexual gratification with the use of objects, most commonly women’s under-garments, shoes, stockings, or other clothing items.

### **Frotteurism**

Individuals with this disorder are gratified by touching or rubbing a non-consenting person. This behavior often occurs in busy, crowded places, such as on busy streets or on crowded buses or subways.

### **Pedophilia**

Pedophilia involves sexual activity with a child, generally under age 13. The DSM-IV-TR describes a criterion that the individual with pedophilia be over 16 years of age and be at least 5 years older than the child. Individuals with this disorder may be attracted to either males or females or both, although incidents of pedophilic activity are almost twice as likely to be repeated by those individuals attracted to males. Individuals with this disorder develop procedures and strategies for gaining access to and trust of children.

### **Sexual Masochism**

Masochism is a term applied to a specific sexual disorder but which also has a broader usage. The sexual disorder involves pleasure and excitement produced by pain, either inflicted by others or by oneself. It usually begins in childhood or adolescence and is chronic. An individual with this disorder achieves gratification by experiencing pain. The term comes from the name of a 19th century Austrian writer, Leopold von Sacher-Masoch, whose novels often included characters who were obsessed with the combination of sex and pain.

In the broader sense, masochism refers to any experience of receiving pleasure or satisfaction from suffering pain. The psychoanalytic view is that masochism is aggression turned inward, onto the self, when a person feels too guilty or is afraid to express it outwardly.

### Sexual Sadism

A sadistic individual achieves sexual gratification by inflicting pain on another person.

The disorder was named after Marquis de Sade, an 18th century French author and military officer who was repeatedly imprisoned for his violent sexual acts against women. In psychoanalytic theory, sadism is related to the fear of castration, while the behaviorist explanation of sadomasochism (the deviant sexual practice combining sadism and masochism) is that its constituent feelings are physiologically similar to sexual arousal. Separate but parallel descriptions are given for sexual sadism and sexual masochism in the DSM-IV-TR. The clinical diagnostic criteria for both are recurrence of the behavior over a period of at least 6 months, and significant distress or impairment of the ability to function as a result of the behavior or associated urges or fantasies. Either type of behavior may be limited to fantasies (sometimes while one is engaged in outwardly non-deviant sex) or acted out with a consenting partner, a non-consenting partner, or in the case of masochism, alone. Sadomasochism occurs in both males and females, and in both heterosexual and homosexual relationships.

### Transvestic Fetishism

This disorder is characterized by heterosexual males who dress in women's clothing to achieve a sexual response. The activity may begin in adolescence, and in secret; later, as an adult, the man may dress as a woman completely and in public. Not all men who cross-dress are unhappy with their gender, but some are. In a small minority of men with transvestic fetishism, gender dysphoria (unhappiness with original gender) may emerge, and those men may eventually seek hormonal treatments or surgical sex reassignment to enable them to live permanently as women.

### Voyeurism

Voyeurism is a paraphilia in which a person finds sexual excitement in watching unsuspecting people who are nude, undressing, or having sex. Voyeurs are almost always male and the victims are usually strangers. A voyeur may fantasize about having sex with the victim but almost never actually pursues this. The voyeur may return to watch the same stranger repeatedly, but there is rarely any physical contact.

Voyeurs are popularly known as "Peeping Toms," based on the 11th century legend of Lady Godiva. According to the story, Tom was a tailor who "peeped" at Lady Godiva as she rode naked through the streets of Coventry, England, in a sacrificial act to get her husband to lower taxes.

### Uncommon Paraphilias

**Bestiality:** Bestiality is a term that describes sexual feelings or behaviors involving animals. Termed zoophilia by DSM-IV this is an uncommon disorder. The disorder does not specify an animal or category of animals; the person with zoophilia may focus sexual feelings on domesticated animals, such as dogs, or farm animals, such as sheep or goats.

**Necrophilia:** Necrophilia is a term that describes sexual feelings or behaviors involving corpses.

**Special Note:** Homosexuality (gay and lesbianism) was previously listed as a paraphilia in the DSM-I and DSM-II, but this was declassified from both DSM-III and DSM-IV,<sup>8</sup> consistent with the change of attitude among psychiatrists and psychologists. Homosexuality is no longer considered a paraphilia.

### GENDER IDENTITY DISORDER

Diagnostic criteria of gender identity disorder as enumerated in DSM-IV include a stated desire to be the other sex, a desire to live and be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex. In adults, the disturbance is manifested by symptoms such as the preoccupation of getting rid of primary and secondary sexual characteristics and the request for hormones, surgery or procedures to alter physically the sexual characteristics to simulate the other sex. This condition of trans-sexual identity should be persisting for at least 2 years and not be a symptom of other psychiatric disorder and not associated with chromosomal abnormality or a physically intersexed condition. Gender identity disorder, thought to be rare earlier,<sup>60</sup> is being increasingly recognized and many thousand cases have been reported. Many trans-gender individuals may themselves present to the medical practitioner with a request for treatment.

During the past 30 years, the recognition of trans-sexualism or gender identity disorder as a treatable condition requiring psychiatric, endocrine, and surgical intervention has been accepted. Harry Benjamin International Gender Dysphoria Association, the professional body dedicated to the study and treatment of trans-sexualism, has set guidelines known as the "standards of care" which includes, in addition to ongoing psychiatric or psychological monitoring, possible endocrine therapy and depending on the outcome of the graduated trial period of cross-gender living, and possible sex reassignment surgical procedures. The philosophy of treatment is to do reversible procedures before the irreversible ones. Thus clothing change, name change, and cross-gender role socialization would precede endocrine treatment with its gradual somatic changes, followed in carefully selected cases, by surgical treatment.

### Sexual Behaviour in Modern Times

In women with Victorian values sexual responsiveness from them was hardly expected (heightened response even disapproved of) and the effort was to achieve orgasm as soon as possible after

commencement of sexual act. In modern times with the increased expectations of women to have rave or wild sex the stress on the man as performer has increased leading to performance-related anxiety and its consequences. Still more problems have come up with the society opening up on sexual issues, women empowerment, availability of sex toys and sexual pleasure enhancing drugs and gadgets which may take the satisfaction levels to new heights and raise the expectations from the next/new partner. Eventually, the search for the sexual performance boosters continues.

## APHRODISIACS

Aphrodisiacs were agents believed to increase sexual desire<sup>61</sup> and derived its name from Aphrodite, the Greek goddess of love, beauty, and sexual rapture.

The search for such substances dates back millennia. Variety of food, drinks, and animal and vegetal derivatives has been used for this purpose by folk medicines of different cultures. Many substances are used for this purpose: alcohol,<sup>62</sup> opiates (morphine and heroin),<sup>63</sup> cocaine,<sup>64</sup> marijuana,<sup>65</sup> alkyl nitrates.

## Alkyl Nitrites

“Poppers” is a colloquial term for various alkyl nitrites inhaled for recreational purposes, particularly amyl nitrite, butyl nitrite, isopropyl nitrite, and isobutyl nitrite. Amyl nitrite is used medically as an antidote to cyanide poisoning<sup>66</sup> but the term “poppers” refers specifically to its recreational use. These products have also been part of the club culture from the 1970s disco scene to the 1980s and 1990s rave scene. Poppers have a long history of abuse due to the rush of warm sensations and dizziness experienced when the vapors are inhaled. Most often, poppers are used recreationally by men who have sex with men as a sexual enhancer<sup>67</sup> or by substance abusers.<sup>68</sup> Inhaling nitrites relaxes smooth muscles throughout the body, including the sphincter muscles of the anus and the vagina.<sup>66</sup> It is unclear if there is a direct effect on the brain.<sup>69</sup> Smooth muscle surrounds the body’s blood vessels and when relaxed causes these vessels to dilate resulting in an immediate increase in heart rate and blood flow throughout the body, producing a sensation of heat and excitement that usually lasts for a couple of minutes. Alkyl nitrites are often used as a club drug or to enhance a sexual experience (70). The head rush, euphoria, and other sensations that result from the increased heart rate are often felt to increase sexual arousal and desire.<sup>70</sup> It is widely reported that poppers can enhance and prolong orgasms. While anecdotal evidence reveals that both men and women can find the experience of using poppers pleasurable, this experience is not universal;<sup>71</sup> some men report that poppers can cause short-term erectile problems.

## PDE5 INHIBITORS

Sildenafil citrate, a member of the phosphodiesterase type 5 inhibitor family of drugs, is perhaps the latest drug to be used in the search for sexual stimulation. Released by Pfizer with

commercial name Viagra in 1998, sildenafil citrate is the first drug for male erectile dysfunction to be approved by the U.S. Food and Drug Administration. Researchers noticed that the drug seemed to have pronounced success in causing erections.<sup>72,73</sup> Within 2 months after its release there were more than one million prescriptions for Viagra. Despite its billing as an anti-impotence drug, many women are also interested in Viagra to learn if the drug will boost their libidos. PDE5 Inhibitors viz. Sildenafil,<sup>74</sup> Tadalafil,<sup>74</sup> and Vardenafil<sup>75</sup> work by inhibiting the breakdown of GMP-specific phosphodiesterase. This in turn enhances the availability of nitric oxide, which figures in a chain reaction that leads to relaxation in the penis’s smooth muscle, causing an erection.

## DATE RAPE DRUG

The term “date rape drug” refers to a drug that can be used to assist in the commission of a sexual assault or rape. Drugs used may have sedative, hypnotic, dissociative, and/or amnesiac effects, and can be added to a food or drink without the victim’s knowledge. The reasons for drink spiking range from personal amusement or maliciousness to theft or (sexual) assault.<sup>76</sup> The three most commonly used drugs for date rape are alcohol and two other hypnotics viz., GHB, (gamma-hydroxybutyric acid), and benzodiazepines (such as flunitrazepam, also known as *Rohypnol* or “roofies”)<sup>77</sup>; however, an American study showed that alcohol still remains the drug most frequently implicated in substance-assisted sexual assault.<sup>78,79</sup>

## SEX TOYS

Sex Toys are the objects or devices that are primarily used to facilitate human sexual pleasure. The most popular sex toys are designed to resemble human genitals and may be vibrating or non-vibrating. However, the form is not applied to items used for birth control, pornography, or to condoms.<sup>80,81</sup>

A large range of sex toys are available in the commercial market to suit the needs of everyone:

1. Vibrators are vibrating devices intended to pleasurablely stimulate various parts of the body. For sexual use they are often dildo-shaped, although they also come in a wide range of other shapes and sizes.
2. “Artificial vaginas,” also known as “pocket pussies” or “masturbators,” are modeled to accept a penis for simulated intercourse. They can be shaped like vaginas, anuses, or anything with a hole for penetration.
3. A nipple clamp is a clamp used to stimulate the nipples by applying varying degrees of pressure.
4. Butt Plugs are often shorter dildos intended for anal insertion. They tend to have a flared base to prevent the device from becoming lodged in the rectum.

**Sex doll** (also called **love doll** or **blow up doll**)<sup>80,82</sup> is a type of sex toy in the size and shape of a sexual partner for aid in masturbation. The sex doll may consist of an entire body with

face, or just a pelvic part, with the accessories (vagina, anus, mouth, penis) for sexual stimulation. The parts are sometimes vibrating and may be removable or interchangeable.

## Conclusion

Thus it is apparent that the variety of forms of expression of human eroticism is great. They defy schemes of classification. Defining what is sexually normal is highly problematic in any operational sense. The consequential differences between those who seek treatment and those who do not complicates the issue more in clinical practice.<sup>65</sup> In summary management of people with sexual problems is so enmeshed with sociocultural, moral, ethical, legal, and political considerations as to require the clinician to draw upon a diversity of perspectives and skills in order to be effective and to achieve a degree of professional competence in working with these people.

## Acknowledgement

The author acknowledges, with gratitude, the help/assistance extended by Dr. S. Balaram Babu in the revision of this chapter.

# Homosexuality, Bisexuality, and Sexual Orientation

David Bradford

99

## Introduction

*"I don't think homosexuality is exactly normal"*—The *British Medical Journal* in 1994 published the results of a study of 28 doctors (20 gay and 8 non-gay) examining homophobia in the medical profession.<sup>1</sup> One non-gay doctor professed not to be prejudiced against homosexuals, but admitted, "Curiously while I am saying this, I don't think homosexuality is exactly normal."

It is over 35 years since the American Psychiatric Association removed homosexuality from its list of psychiatric disorders, but many doctors and health professionals around the world still share the ambivalent feelings of the doctor quoted above. Venereologists and specialists in sexual health medicine are not immune from these feelings despite their experience in dealing with patients exhibiting a wide spectrum of human sexual desire and behavior. Such doctors are not profoundly homophobic; they just find homosexuality and related diverse sexualities (bisexuality, transvestism, and transsexualism) difficult to understand and mildly to moderately uncomfortable to deal with. However, their ambivalent and uncomfortable feelings come across to their differently sexed patients in a thousand subtle ways—in body language, in nuances of verbal expression, and in the way they conduct their clinical management of such patients. Their approach reinforces the attitudes of general society that these people are different, these people are "other," these people are "not exactly normal." And in so doing, health practitioners render their patients a major disservice and potentially harm the public health. This chapter aims to show that ambivalent, uncomfortable or frankly negative feelings on the part of health practitioners to their homosexual or bisexual patients are irrational and harmful, and to point the way towards better medical management.

Homosexual and bisexual men and women are ordinary everyday members of the human race. They are not predatory and they are no more likely to be sex offenders or to engage in pedophilic behavior than their heterosexual peers. In fact, almost all sex offences against children are committed by men and most of these are against female children.<sup>2</sup> Homosexual and bisexual men and women have never threatened the social order and its

institutions, have never been a danger to the prevailing culture and have no inherent bias against religious customs; on the contrary, it has been individual societies which traditionally have criminalized homosexual behaviors and stigmatized individuals of diverse sexuality. A multiplicity of cultures has decreed homosexual activity as aberrant. And most major religions have implacably opposed homosexual practices and expelled homosexual and bisexual men and women from congregations of the faithful (as well as, in most cases, consigning them to eternal damnation). The vehemence and malignity of antihomosexual feeling in so many cultures and countries across the world is difficult to explain on any rational basis and has led (and continues to lead) to much needless and undeserved suffering. It is incumbent on healthcare practitioners to do all they can to alleviate this suffering and to take a stand against homophobic attitudes and practices in society.

## Definitions

The terms homosexuality, bisexuality, sexual orientation, and sexual identity are bedevilled by confusion. The definitions given below may explain the difficulties.

### HOMOSEXUALITY AND HOMOSEXUAL ORIENTATION

To describe a person as "homosexual" can have three rather subtly different meanings:

1. "Homosexual" can describe a person's sexual *behavior*—i.e., a person who predominantly or exclusively has sex with a person or persons of the same sex can be said to be homosexual in *behavior*. Many people whose behavior falls into this category do *not* regard themselves as being homosexual; however, the rather clumsy terms "men who have sex with men" (MSM) or "women who have sex with women" (WSW) have been conjured up to allow meaningful discussion of such activity. Behavioral research occasioned by the human immunodeficiency virus (HIV) pandemic was largely responsible for the development and widespread use of the term "MSM."

2. “Homosexual” can describe a person’s sexual *preference*—i.e., a person whose sexual desire is predominantly directed towards members of the same sex can be said to be homosexual in *orientation*. Because we cannot see into a person’s mind, and because desire or preference might not translate into overt activity, we do not know what an individual’s sexual preference might be unless she or he agrees to divulge that information about themselves. It is probable that a significant proportion of the population prefer to keep their true sexual desires and yearnings secret.
3. “Homosexual” can describe a person’s sexual *identity*—i.e., a person who adopts a sexual life style which is consistent with and self-defined by same sex desire and same sex behavior can be said to have a homosexual identity. Males who adopt a homosexual identity are often referred to as gay while females who adopt a homosexual identity are referred to as lesbian.

## BISEXUALITY

Bisexuality is even less clearly defined than homosexuality, but the term can have three rather different meanings:

1. “Bisexual” can describe a person’s sexual *behavior*. It is obviously a term that can be applied to a person who has sex with both males and females. In this strict sense, a significant number of people who would prefer to describe themselves (or identify) as either “homosexual” or “heterosexual” might demonstrate bisexual behavior intermittently or even on a regular basis.
2. “Bisexual” can describe a person’s sexual *preference* or desire—i.e., a person whose sexual desire is directed towards members of both sexes can be said to be bisexual in *orientation*. The same caveat that applies to meaning number 2 for “homosexuality” equally applies here.
3. “Bisexual” can describe a person’s sexual *identity*—i.e., a person who adopts a sexual life style, which is consistent with and self-defined by sexual desire for persons of both sexes and sexual behavior with members of both sexes can be said to have a bisexual identity.

Meaning number 3—sexual *identity*—is very much a western social construct and may have little relevance or meaning outside industrialized western countries. Large parts of the adult population of the world get by very nicely without having to define themselves as “gay” (a homosexual man), “straight” (a heterosexual man or woman), “bisexual” (man or woman who is sexually versatile) or “lesbian” (a homosexual woman). They regard themselves merely as men or women and do not seek to create a specific identity based on their predominant (or occasional) sexual activities or desires. Although nature itself never stoops so low, western culture disliking disorder and messiness feels the need to “tidy people up”—especially minorities, and get them into correct boxes with the right labels attached.

## OTHER NON-WESTERN SEXUAL IDENTITIES

In parts of the world other than the industrialized west, some minority groups of biological males adopt other gender roles from time-to-time or continuously. These groups may be visible as men who act in an exaggeratedly effeminate manner or who dress and behave as women. Such men may participate in sexual activity with other men and may indeed attract male sexual partners from other groups of males in the community who act in an exaggeratedly masculine manner but yet predominantly choose to have sex (where they assume the “male” insertive role) with men from cross dressing or effeminate groups. These groups defy conventional categorization but can all be described as men who have sex with men (MSM).

In the Indian subcontinent, the most prominent groups are:

- *Hijras*—transgendered MSM, sometimes regarded as a “third sex.” They are often castrated, dress as women and are part of a clearly identified social group, which is tolerated by society but sometimes feared as well.
- *Kothis* (also called *Metis* in Nepal)—these are MSM who adopt an effeminate lifestyle but who nevertheless may be married and father children.
- *Panthis* (also called *Ta* in Nepal)—these are masculine men who although passing as ordinary males in the community sometimes have insertive sex with *Kothis*. They do not self identify but are labeled or nick-named *Panthis* by the *Kothis*.

In Southeast Asia, there are many groups of MSM, but some of the more prominent and better known ones include:

- *Katoey* (Thailand and Laos), *Kteuy* (Cambodia), and *Waria* (Indonesia)—these are transgendered MSM, sometimes cross-dressing and sometimes engaging in sex work where they attract a sub-group of masculine males who prefer sex with transgendered men.
- *Sray sros* (Cambodia)—these are men who identify as women and who dress as women to attract male sexual partners. They are also known as “long hairs” in English.
- *Pros saat* (Cambodia)—these are masculine acting MSM (also called “short hairs” in English) who may choose to have sex, where they adopt the masculine insertive role, with *Sray sros*.<sup>3</sup>

## Etiology

Theories abound about the origin of homosexuality. Factual knowledge is far more elusive. Given the enormous diversity of sexual desire and behavior in human beings around the world it is not surprising that so little is known about causative factors. Any successful theory about the origin of homosexual desire must account for the curious fact that homosexuality and bisexuality are such persistent human traits. By the very nature of exclusive same-sex sexual activity there would seem to be no evolutionary advantage—rather the reverse. Why did homosexual tendencies not die out centuries ago? We have seen already that human societies and cultures, with very few exceptions, have been

implacably opposed to the expression of a homosexual lifestyle, yet people with same sex desires have persistently and inexplicably done what comes naturally to them in every country, under widely varying cultures and throughout all epochs of time, often to their considerable individual disadvantage. The sex drive is deep and strong and the libido will have its way whatever the consequences! Carl Westphal (1833–1890), the Berlin psychiatrist with the dubious honor of being the first medico to label homosexuality a disease, at least recognized the existence of an “instinctive urge stronger than the will, driving some individuals to find sexual pleasure with others of the same sex.”<sup>4</sup> Despite the inherent fascination in the topic, for the limited purposes of this Chapter we can get little further than the not so profound summing up in a 2006 article: “Finally I argue that exclusive same sex attraction in human males is due to an interaction between genetic, cultural, developmental, and psychological factors.”<sup>5</sup>

## Prevalence of Homosexuality and Bisexuality

The prevalence of homosexuality and bisexuality depends upon the definition the researcher is adopting. Clinicians who work in sexual health are more interested in homosexual and bisexual *behavior* than they are in sexual identity or preference because it is behavior which places people at risk for sexually transmissible agents, including HIV. Social biologists, psychologists, and anthropologists on the other hand will be interested in sexual preference and identity as well as behavior.

In several western countries, large population surveys of adult sexual behavior have been carried out in the past decade or two. These have revealed that the percentage of males and females who identify as gay, bisexual or lesbian is small. The Australian Study of health and relationships found that only 1.6% and 0.9% of men *identified* as homosexual or bisexual respectively, while 0.8% and 1.4% of women *identified* as homosexual or bisexual.<sup>6</sup> These figures accord well with similar studies done in other western countries.<sup>7</sup>

However higher percentages of people, including people who identify themselves as heterosexual, report same-sex *desire* or attraction. The Australian study reported 8.6% of men had experienced some same-sex attraction or some sexual experience with another male, while 15.1% of women had felt sexually attracted to other women or had some sexual experience with the same sex.<sup>6</sup>

In other parts of the world, and particularly in Asia and Southeast Asia, the true prevalence of same-sex sexual behavior is unknown. Homosexuality and bisexuality remain largely invisible within mainstream society because the socially recognized categories in the West such as gay, lesbian or bisexual around which men who have sex with men and women who have sex with women can frame their sexuality do not exist. In these countries MSM and WSW form extremely heterogeneous populations marked by a diversity of sexual self-perception and sexual activity.<sup>8</sup> While there are no published estimates of the prevalence of female same-sex behavior anywhere outside western countries,

population-based studies have suggested that the prevalence of male–male sexual activity in Asia is similar to or higher than that established for the West, and that large numbers of MSM also have sex with women. AmfAR’s 2006 Report ‘Treat Asia’ comments wryly “Asia has more than enough male–male sex to fuel an (HIV) epidemic.”<sup>3</sup>

## Homosexuality and Clinical Practice

For the practising healthcare provider, academic debate about the nature of homosexuality or bisexuality is largely non-productive and unhelpful. Homosexual desire and same-sex sexual activity are simply facts of life, as they have always been. Yet homosexual desire and behavior exert an influence on the health of those affected which can have far reaching effects both for the individual and the public health. A young person who reaches the turmoil of puberty and adolescence and discovers that her or his sexual desires are directed towards members of the same sex (as is the case for 8–15% of that population<sup>6</sup>) can find this a troubling and isolating experience. If that young person is fortunate and lives in a family and a culture where homosexuality and bisexuality is recognized as part of the normal wide spectrum of human sexual orientation and behavior, then she or he is likely to weather the storm well. But if, as will be the case for most young people around the world, she or he lives in a family and a culture where homosexual desire and behavior are regarded as abnormal, abhorrent or even evil, the effects on that young person’s mental, physical, and sexual health may be serious and even life-threatening. The link between youth suicide and homosexuality particularly in young men is now well established.<sup>9</sup> Where sexual behavior is stigmatized, the societal pressures brought to bear on those whose sexual desires force them to act beyond the bounds and limits set by prevailing social mores are very strong—strong enough indeed to lead to deep depression and suicidality in vulnerable individuals. For others who reach some adjustment and accommodation with their sexuality, the fact of their sexual difference in a hostile environment means they have to resort either to a life of repression where their true sexual desires and needs are never met, or a double life—a life that on the surface accords with society’s demands but covertly includes stratagems, which allow the individual some sexual relief usually in clandestine and anonymous associations with like-minded men or women. These two main methods of coping—either sexual repression or trying to lead a double life—can place strains on people which can be barely tolerable over time and may result in substance abuse or poor health. There is good evidence that alcohol abuse and nicotine dependence are commoner in homosexual men and women. Cardiovascular disease and mental health problems are also more common than in heterosexual peers.

## Sexual Health and Homosexual or Bisexual People

Women who have sex with women (WSW) and who never have sex with male partners seem relatively free of sexually

transmitted infections (STIs). However, infections that do not require penetrative sex for transmission (like human papilloma virus [HPV] and the herpes simplex viruses [HSV1 and HSV2] for example) are theoretically capable of being passed on by woman-to-woman sexual contact and indeed are seen in clinical practice in WSW. The curious condition bacterial vaginosis (BV) is also significantly associated with WSW. HPV infection of the cervix can be acquired through sexual activities between lesbian women so even exclusive WSW should be advised that they still require regular cervical cytology (Pap Smears). Bisexual WSW are obviously at the same risk of STIs as exclusively heterosexual women and the risk depends on whether male partners carry any sexually transmissible micro-organisms.

STIs, including human HIV infection, have always been a significant blight on the lives of men who have sex with men (MSM). There are strong hints from the writings of classical authors of Greece and Rome that this fact was recognized even then. In 2008, UNAIDS reported that HIV infections among MSM were increasing sharply in parts of Asia and that only 40.1% of MSM in 27 reporting countries were reached by HIV prevention programs between 2005 and 2007.<sup>10</sup> A grave crisis now exists in the explosion of HIV infection rates among MSM throughout the whole of the Asian continent.

This fact is not surprising; Table 99.1 lists the biological and sociological reasons why STIs are common in MSM, especially in homophobic societies.

We clinicians cannot escape censure. Unfortunately, there are also strong medical reasons why STIs and HIV remain uncontrolled in MSM (see Table 99.2). These facts are applicable in all countries and societies and are not just confined to regions where homosexual behavior is illegal and stigmatized. Clinical testing and management of patients giving a history of male–male sexual activity is covered in other chapters in this textbook, but it is vital to stress that the clinician's overall attitude towards MSM patients is important not just for the individual patient's benefit but also for the public health. Because world-wide, a high percentage of MSM also have sex with women, the potential for wider spread of HIV and other STIs through bisexual behavior is great. Good management and early diagnosis and treatment of MSM for STIs will do much to reduce this risk.

## Conclusion

Homosexuality and bisexuality are part of the human condition. The quality of the relationship between countless same-sex couples down through the centuries (some famous and well-known people, most obscure and ordinary folk) attests to the fact that homosexual love can be as strong, deep, and lasting as heterosexual love. Love between adult individuals should always be respected and should never be criminalized. Sex is a vital essential part and expression of love. Society's refusal to accord same-sex love the respect and equality given to heterosexual love has been the direct cause of almost all the problems attributed to homosexual behavior in the past and down to the present time. In this matter,

**Table 99.1:** Reasons for High Prevalence of STIs in Men Who Have Sex With Men

Biological
Men possess a penis
Penises are penetrative organs
Penises are designed to transmit semen (along with anything else in seminal fluid!)
Highly receptive columnar epithelial surfaces are involved in male-to-male sex: <ul style="list-style-type: none"> <li>• Rectal mucosa</li> <li>• Anorectal squamo-columnar junction</li> <li>• Oropharyngeal and tonsillar mucosa</li> <li>• Urethral meatal mucosa</li> <li>• Inner surface of prepuce (foreskin)</li> </ul>
Sociological
Myths and ignorance abound about male-to-male sex—e.g., in countries where HIV transmission is predominantly heterosexual, many men believe sex with men is safer
Barrier protection is not needed to prevent reproduction, so condom use is rare
Illegality discourages open expression of male-to-male love or sexual behavior
Societal stigmatization directly discourages regular open relationship between two males
Societal stigmatization thus indirectly encourages multiple casual partners
Male-to-Male sexual activities are often covert: <ul style="list-style-type: none"> <li>• Fleeting opportunistic contacts</li> <li>• Frequently contacts are anonymous</li> <li>• Frequent concurrent disinhibiting substance use (especially alcohol)</li> <li>• Sex may be in dimly lit places, so partner not clearly seen; protection difficult</li> <li>• Opportunistic male-to-male sex work common in homophobic societies</li> </ul>

**Table 99.2:** Medical Reasons for Poor Control of STIs (& HIV) in MSM

Patient-centred	Clinician-centred
Shame and guilt	Discomfort with homosexuality
Lack of self-esteem	Ambivalent feelings about MSM
Fear of clinician's disapproval	Judgemental or moralistic approach
Fear of consequences of self-disclosure	Irrational fear of contamination from MSM
Decreased health seeking behavior	Not swabbing the correct anatomical sites
Giving an untrue sexual history if symptomatic	Ignorance about testing and management of STIs in MSM

society is clearly behaving irrationally. In the words of Australia's recently retired High Court Judge, Justice Michael Kirby: "this irrationality has to stop, the denial and hatred have to come to an end."<sup>11</sup>

## Introduction

Clinical and epidemiologic studies exploring sexual attitudes, behaviors, and clinical conditions among women who have sex with women (WSW) are lacking. Existing literature, though sparse, does contain important findings in the field of sexually transmitted infections (STI) among WSW. This chapter highlights sexual health risks and clinical conditions among WSW.

It is worth exploring terminology in the arena of sexual health among WSW. There are three terms that deserve description: sexual orientation, sexual identity, and sexual behavior. Each of these conveys information about an individual's same-sex attraction and behavior and is readily confused with each other. According to the American Psychological Association, sexual orientation describes emotional, romantic, or sexual attraction toward others.<sup>1</sup> This may be different than sexual identity, which is how a person labels oneself in terms of a place within a specific community (lesbian, bisexual, or queer, for example). Sexual behavior describes specific sexual practices despite orientation or identity, and is most relevant when attempting to estimate risks of incident disease in the context of STI.

Terms commonly used in the scientific literature include "WSW" to refer to women whose primary sexual partnerships are with women, and "WSMW" to refer to women who report sex with men and women. However, the time frame over which sexual contact with men is used to differentiate between these two designations can differ considerably among studies, ranging from the past 90 days through a woman's lifetime. Thus, no universal definitions exist for WSW and WSMW.

## Epidemiology

Data collection occurring as part of most large epidemiologic studies has largely omitted specific categorization of WSW. In the US, two landmark women's health surveillance projects, the Women's Health Initiative (WHI) and the Nurse's Health Study, only began collecting information on same-sex behavior or identity in 1998 and 1995, respectively (DHHS, 2000). More recently, population-level data have become available for some industrialized countries.

According to the US National Survey of Family Growth from 2002, 11% of women aged 15–44 reported same-sex behavior in their lifetime. This report was based on a sample of 12,571 men and women and collected information of sexual behavior using audio computer-assisted self-interviewing (A-CASI).<sup>2</sup> In Britain, the National Survey of Sexual Attitudes and Lifestyles (NATSAL) 2000 study collected information on the sexual behavior of 11,161 residents age 16–44.<sup>3</sup> Of the female respondents, 4.9% reported same-sex behavior including genital contact and 2.8% reported some same-sex behavior in the past year. Notably, 98% of WSW reported a history of sex with men at some point in their lifetimes and 85% reported that they have had sex with at least one man in the past 5 years. In a study conducted in 2003 in Australia of 9134 randomly selected women between 16 and 59, 0.8% of them identified as lesbian, 1.4% as bisexual, and 15.1% reported same-sex attraction or sexual experience.<sup>4</sup> No data are available on the prevalence of WSW in resource-limited countries, despite a recent burgeoning of information on report of same-sex behavior among men in sub-Saharan Africa.<sup>5,6</sup>

## Risk Behaviors

According to multiple studies, the majority of WSW (between 80% and 95%) report a sexual history with men, with much of this behavior commencing during adolescence.<sup>7,8</sup> Diamant and colleagues surveyed 6935 self-identified lesbians solicited through a survey printed in *The Advocate*, a US-based national gay and lesbian news magazine. The majority of women in this study (77.3%) reported one or more lifetime male sex partners. Of these women, 17.2% reported having anal intercourse and 5.7% reported a male sex partner in the past year.

Alcohol abuse, illicit drug use, and exchange of sex for drugs or money are known high-risk behaviors that are suggested to be more prevalent among WSW.<sup>9–14</sup> One relatively large cross-sectional survey across healthcare sites in the US found that women who identified as lesbians reported more male sex partners and higher numbers of homosexual male sex partners in the past year than either heterosexual or bisexual women.<sup>15</sup>

**Table 100.1:** Risks and Characteristics by Report of Drug Use in the Past Year

Behavior/Clinical characteristic	Methamphetamine RR (95% CI)	Cocaine RR (95% CI)	MDMA (Ecstasy) RR (95% CI)	Heroin RR (95% CI)	Marijuana RR (95% CI)
Sex with any new male SP, 60 days	3.17 (1.4–7.1)*	3.46 (1.8–6.5)*	2.74 (1.4–5.4)*	3.81 (1.2–11.8)	1.69 (0.8–3.5)
Vaginal intercourse with a male SP, 90 days	2.40 (1.4–4.1)*	2.70 (1.8–4.0)*	2.49 (1.6–3.8)*	1.79 (0.6–5.3)	2.21 (1.3–3.7)*
More than 1 male SP, 90 days	3.61 (1.1–9.1)*	4.64 (2.0–10.6)*	3.87 (1.6–8.8)*	5.45 (0.9–12.5)	6.58 (1.6–40.5)*
Anal sex, male or female SP, 90 days	1.50 (1.1–2.0)*	1.31 (1.1–1.7)*	1.35 (1.0–1.7)	0.77 (0.3–2.3)	1.14 (0.9–1.5)
Self-reported history of <i>C. trachomatis</i> infection	4.56 (1.7–12.2)*	2.95 (1.2–7.1)*	3.01 (1.2–7.6)*	3.18 (0.5–19.4)	2.32 (0.8–6.9)
Reporting ever having traded sex for money or drugs	4.25 (1.5–9.5)*	3.43 (1.5–7.6)*	1.2 (0.3–3.3)	10.8 (3.7–14.0)*	1.00 (0.4–2.3)

\* $P < 0.05$  Abbreviations: RR, relative risk; SP, sex partner.

This study included 1304 lesbians across 33 outpatient primary care sites who completed an extensive questionnaire (98 items) with a good response rate (>50%). Respondents were mostly white, highly educated, and had a relatively high income. Although most women reported being in a stable relationship (71%), many (23%) reported substance use while having sex or sex with a homosexual or bisexual man (6%) in the past year. Of those women who recently had sex with men ( $N=600$ ), only a little over half reported ever using condoms. Table 100.1 details findings from one analysis in Seattle, Washington, US, on use of illicit drugs among 336 WSW and WSMW aged 16–35 years. Use of MDMA (ecstasy), methamphetamine, and cocaine were all associated with sex with new male partners, multiple male partners and self-reported history of *Chlamydia trachomatis* (*C. trachomatis*) infection. Also, use of methamphetamine and cocaine were associated with increased risk of recent anal sex.<sup>16</sup>

Consistent with sexual histories with men, lifetime prevalence of reported pregnancy ranges from 23% to 35% among WSW.<sup>17,18</sup> Among 392 WSW who participated in the Seattle Lesbian Health Study (1998–2001; median age of all subjects, 28 years), 25% reported a prior pregnancy, over half had used oral contraceptives, and 16% had had an induced abortion.<sup>19</sup>

Specific higher risk sexual behaviors among WSW in Britain were reported in the NATSAL 2000 study.<sup>3</sup> Interestingly, WSW who reported male partners, as compared with heterosexual women, more commonly reported anal sex (age-adjusted odds ratio for WSW relative to women reporting exclusively heterosexual partners [AOR] 2.46 [95% CI 1.58–3.85,  $P < 0.001$ ]). Similarly, WSW, when compared with heterosexual women, most commonly reported a recent partner described as “not regular” (AOR 1.74 [95% CI 1.07–2.82,  $P = 0.02$ ], initiating sex less than 24 hours after meeting most recent partner (AOR 2.48 [95% CI 1.44–4.27,  $P = 0.001$ ]) and unsafe sex (two or more heterosexual partners in the past 4 weeks with inconsistent condom use; AOR 7.17 [95% CI 3.25–15.8,  $P < 0.001$ ]). Moreover, WSW were more likely than heterosexual women to report seeking care at an STD clinic, obtaining an HIV test, being diagnosed with any STI and having had an induced abortion ( $P < 0.001$  for each relative to heterosexual respondents).

Interestingly, studies that have evaluated same-sex behavior among adolescents in the US have found some disparate findings between WSW and WSMW. In one study of more than 29,000 sexually active female college students, self-identified bisexual women reported a history of more STIs than either their heterosexual or self-identified lesbian counterparts.<sup>20</sup> In one analysis among WSW 14–44 years of age, self-reported viral STI rates were significantly higher among self-identified bisexual women (15.0–17.2%) than among self-identified lesbians (2.3–6.7%).<sup>21</sup> These findings support the need to carefully assess sexual history in terms of prior and current risk behavior for more focused and optimal screening and education.

## Sexual Behaviors and Sexually Transmitted Infections

Table 100.2 provides an overview of sexual behaviors commonly practiced by WSW. The consensus from the available data is that over 95% of WSW engage in oral-vulvar/vaginal sex (cunnilingus) or oral-anal sex (anilingus). These activities provide the opportunity for transmission of a variety of pathogens. There was an outbreak of *Entamoeba histolytica* in Canada among WSW and WSMW engaging in oral-anal sex, providing evidence of the broad possibilities of transmission of enteric pathogens.<sup>22</sup> WSW also commonly practice digital-vaginal sex and digital-anal sex (“fingering” or “fisting”) and frequently also use sex toys inserted vaginally and/or anally. The proportion of women who engage in sadomasochism is unclear, but this behavior obviously may expose women to exchange of blood.

Many of the sexual behaviors practiced by WSW present a plausible means for exchange of infected cervicovaginal secretions and blood if barriers are not used. This possibility is supported by reports of transmission of genital human papillomavirus (HPV), genital herpes, *C. trachomatis*, syphilis, trichomoniasis, and HIV among this group.<sup>23–28</sup> Despite these reports and studies over the past two decades that describe STI among WSW, many women and healthcare providers remain under the false assumption that WSW are at no risk.

Other sexual behaviors that WSW commonly practise include mutual masturbation, kissing, and massage. Additionally,

**Table 100.2:** Sexual Practices among Women who have Sex with Women<sup>10,22,59,72</sup>

Practice	Vernacular name	Estimated frequency <sup>10,22,59,72</sup>	Factors modifying risk of STD <sup>†</sup>
Oral-vulvar/vaginal contact (cunnilingus)	Going down Active = Top Receptive = Bottom	Very common (>95%)	<ul style="list-style-type: none"> <li>• Presence of oral lesions in active partner (herpes, syphilis, possibly gonorrhea) (+)</li> <li>• Use of barriers (plastic wrap, dental dams, condoms)</li> </ul>
Digital/vaginal-contact (digital-anal contact)	Fingering Fisting (top or bottom)	Very common (95%)	<ul style="list-style-type: none"> <li>• Sharing of infected cervicovaginal secretions (trichomoniasis, <i>C. trachomatis</i>, gonorrhea, HPV, herpes) (+)</li> <li>• Use of gloves (–)</li> </ul>
Oral/anal contact	Anilingus Rimming	Common (35%)	<ul style="list-style-type: none"> <li>• Presence of oral infection in performing partner (syphilis, genital herpes) (+)</li> <li>• Presence of anorectal infection in receiving partner (Hepatitis A, <i>E. histolytica</i> and other enteric pathogens) (+)</li> <li>• Use of barriers (–)</li> </ul>
Insertive sex toys (to vagina or anus)	Toys, dildos	Common vaginally (60%) and anally (25%)	<ul style="list-style-type: none"> <li>• Sharing of infected cervicovaginal or anal fluid (trichomoniasis, <i>C. trachomatis</i>, gonorrhea, HPV, herpes) (+)</li> <li>• Use of condoms with sex toys (–)</li> <li>• Sharing insertive toys without cleansing prior to use (+)</li> </ul>
Direct genital-genital contact	Tribadism	Very common (95%)	<ul style="list-style-type: none"> <li>• Direct contact of susceptible skin/mucosa (HPV, herpes, syphilis) (+)</li> <li>• May involve use of interposed devices, such as vibrators, which can cause mechanical vulvar irritation</li> </ul>
Sadomasochism	S & M, Bondage	Unknown	<ul style="list-style-type: none"> <li>• Sharing of blood (hepatitis B, C, HIV) (+)</li> </ul>

\*Refs. 10, 22, 59, and 72.

†Plus sign (+) denotes factor likely to enhance risk of STI transmission or acquisition; minus sign (–) denotes factor with probable protective effect

tribadism or frottage, which is defined as genital rubbing by any part of the other woman's body, often the thighs, legs or trunk, is also commonly practiced but thought to be relatively low risk for transmission of STI. There is, however, theoretical risk of HSV and mite transmission with close mucosal or skin-to-skin contact. (McNair, Sexual Health, 2005) Table 100.3 compares the rates of self-reported or clinically diagnosed STIs in a range of studies. Further discussion on each of these STIs and on bacterial vaginosis (BV) follows.

## GENITAL HUMAN PAPILLOMAVIRUS

Certain strains of HPV cause genital warts, the majority of cervical cancer, and some types of anal cancer. HPV has been detected in WSW, including those with no prior history of sex with men. Two research efforts based in the US (Seattle Lesbian Health Study) enrolled WSW to assess HPV DNA by PCR-based methods in cervical, vaginal, and vulvar samples.<sup>25,27</sup> Among 150 women in the earlier of these two studies (1995–1997), HPV DNA was present in 30% of all subjects and in 19% of those who reported no lifetime history of sex with men. Among all subjects with detectable HPV DNA, 29 (69%) had unclassified types only, 9 (21%) had HPV-31/33/35/39, 8 (19%) had HPV-16, and 1 (2%) had HPV-6/11. Twenty-eight (62%) had HPV DNA detected in the specimens from the cervix, 26 (58%) from the vagina, and 32 (71%) from the vulva. Among the 41 women with HPV DNA who did report prior sex with men, 21 (51%) had not had sex with a male partner in over a year (range, 1–18 years; median, 2 years). Women with detectable HPV DNA who reported male sex partners were more likely to report a history of receptive oral sex ( $P=0.05$ ).

In a follow-up to the initial work on HPV among WSW, researchers in the Seattle Lesbian Health Study enrolled women between 1998 and 2001 and measured HPV DNA in 248 women, detecting it in 31 (13%), including 7 with HPV type 16 and 15 with other oncogenic types. Twelve (39%) had non-oncogenic types (6/11, 40/42/53/54). Among the 28 women with HPV DNA who reported prior sex with men, 14 (50%) had not had sex with a male partner in over a year (range, 1–11 years; median, 2 years). Importantly, both high- and low-grade squamous intraepithelial lesions (SIL) were detected on Pap smear testing in both of these studies, including among women with no history of sex with men. In the first study, 13 (6% of all subjects) of 150 participants had abnormal Pap smears with 3 of these women reporting no prior sex with men and 3 women reporting female partners with genital warts. Among 248 women enrolled in the second study, 7 of 11 SIL detected occurred in women who reported no prior sex with men or sex with men more than 1 year previously. Twenty-five women (10% of all subjects) had abnormal Pap smears. Four women had high-grade and 7 had low-grade SIL with 7 of these lesions occurring in women who reported no history of sex with men or sex with men more than one year prior to testing. HPV DNA was detected in 7 of the 11 women with SIL (HPV-16 in 3 women and other oncogenic types in 4 women). Discussion of Pap smear testing as cervical cancer screening among WSW follows in the section of this chapter on Preventive Health.

## GENITAL HERPES

Both herpes simplex virus (HSV) type-1 and HSV type-2 occur among WSW, with some suggestion that HSV-1 is more

<sup>‡</sup>The STI self-reported rates for this study are reported for the whole study population.

prevalent in this population. Genital herpes is classically caused by HSV-2 but can also be secondary to HSV-1. Among the 392 women enrolled in the Seattle Lesbian Health Study, antibodies to HSV-1 were detected in 46% and antibodies to HSV-2 in 8% as determined by Western blot assay.<sup>26</sup> Moreover, HSV-1 seroprevalence increased significantly with increasing numbers of female partners, suggesting that oral-genital transmission of this virus might be relatively common. Of 78 women who reported no prior sex with men, 3% were HSV-2 seropositive.

Findings from the Seattle study are slightly disparate from those of the US National Health and Nutrition Examination Survey (NHANES) study that tested sera collected between the years 1999 and 2004 on a population presumed to be predominantly heterosexual.<sup>29,30</sup> The seroprevalence of HSV-2 among women age 20–29 years old was 15.6%, roughly double that of the seroprevalence from the Seattle study. This could be explained, in part, by less efficient genital transmission of HSV-2 in the absence

of penile–vaginal sex. Additionally, the Seattle based study largely comprised white women who reported long-term monogamous partnerships. Predictors of HSV-2 infection in the NHANES study included race, age, lifetime number of sex partners (gender not specified), and marital status. Other predictors included fewer years of formal education, income below the poverty level, and history of cocaine use. Of these, increasing age was the only independent predictor for HSV-2 seroprevalence in the Seattle Lesbian Health Study (see Fig. 100.1).

Because genital infection with HSV-1 is most likely acquired during receipt of oral sex, a behavior probably practiced more frequently by WSW than heterosexual women, WSW may be at increased risk. Some studies support that the incidence of genital infection with HSV-1 is increasing and that new genital HSV-1 infections are as common as oropharyngeal HSV-1 infections.<sup>31–34</sup> Receptive oral sex in the absence of vaginal intercourse among 1207 heterosexual women prospectively followed in Pittsburgh increased

**Fig. 100.1:** Seroprevalence of HSV by Number of Lifetime Sex Partners. (With permission from Marrazzo JM, Stine K, Wald A. Prevalence and risk factors for infection with herpes simplex virus type-1 and -2 among lesbians. *Sex Transm Dis* 2003;30:890–5.)

**Fig. 100.2:** Sexual Behaviors of Women who have Sex with Women. (With permission from Marrazzo JM, Stine K, Wald A. Prevalence and risk factors for infection with herpes simplex virus type-1 and -2 among lesbians. *Sex Transm Dis* 2003;30:890–5.)

the risk of HSV-1 seroconversion (9.8 versus 1.2 cases per 100 woman-years of follow-up;  $P=0.04$ ).<sup>35</sup> Data from the Seattle study supported a stronger association between number of lifetime female sex partners and HSV-1 infection (Fig. 100.2) than among those who reported male sex partners in the NHANES study.<sup>30</sup>

### CHLAMYDIA TRACHOMATIS AND NEISSERIA GONORRHOEA

*C. trachomatis* is the most common bacterial STI in the world with a global burden of almost 92 million cases based on a World Health Organization (WHO) estimate from 1999 and an estimated 4–5 million cases in the US alone reported annually to the Centers for Disease Control and Prevention (CDC) in 2009.<sup>36</sup> *C. trachomatis* has a major impact on women's sexual and reproductive health. Untreated infections can lead to pelvic inflammatory disease (PID), tubal infertility, and chronic

pelvic pain. Because the majority of infections in women are asymptomatic and do not cause visible signs of cervicitis, the CDC and the United States Preventive Services Task Force recommend annual screening for all women aged 24 years and younger.<sup>37,38</sup> Despite the widespread prevalence of *C. trachomatis*, little data at the clinic, community or population level is available that describe its prevalence among WSW.

There are no reliable reports of documented transmission of either *C. trachomatis* or *N. gonorrhoeae* among WSW. For example, among 709 new patients attending a clinic for lesbians in London, prevalence of *C. trachomatis* was 0.6% and gonorrhea was 0.3%.<sup>39</sup> Another study based in an STD clinic in Seattle, Washington revealed *C. trachomatis* among only 2 (1.1%) of 187 women reporting sex only with women in the past 2 months and in 12 (1.9%) of 841 women reporting sex with both men and women during that time frame. *N. gonorrhoeae* was detected in 0 of 192 women and 14 (2.1%) of 661, respectively.<sup>18</sup>

More recently, in an analysis of 9358 visits with tests for *C. trachomatis* among WSW and WSMW attending family planning in the US Pacific Northwest from 1997 to 2005, *C. trachomatis* positivity, a proxy for clinic-based prevalence, was 7.1% among both WSW and WSMW compared with 5.3% among heterosexual women tested during the same time frame. Behavioral risks were more commonly reported by women reporting same-sex behavior compared to heterosexual women. WSW with *C. trachomatis* infection were more likely to have clinical findings (including cervical ectopy, friable cervix, PID or cervicitis) (OR 3.5 [95% CI 2.3–5.3],  $P<0.05$ ) compared to WSM (OR 3.1 [95% CI 3.0–3.3],  $P<0.05$ ) and WSMW (OR 2.5 [95% CI 1.7–3.8],  $P<0.05$ ). Risks for *C. trachomatis* positivity were comparable across the groups and included younger age, non-white race, behavioral risks, and clinical signs of infection.<sup>40</sup> The authors concluded that until more data are available to clarify the epidemiology and risks associated with this common infection, WSW should undergo routine age-based screening for *C. trachomatis* as recommended for heterosexual women. It is theoretically plausible that exchange of cervicovaginal secretions between women may provide the opportunity for *C. trachomatis* transmission in this group.

### HUMAN IMMUNODEFICIENCY VIRUS AND SYPHILIS

As discussed in the prior section on sexual risks behaviors, some data suggest that some WSW engage in higher risk sexual behaviors, including sex with men who have sex with men (MSM), relative to their heterosexual counterparts. Given this, some WSW may be at risk for STI prevalent in MSM. Risk of HIV transmission varies with sexual behaviors, including exchange of cervicovaginal secretions, or exchange of blood in the setting of vulvar or vaginal abrasions, during menses or as a consequence of sexual activity.

While no large scale studies have been conducted on WSW and HIV, there have been case reports of HIV transmission between women, including women who report sex exclusively with women.<sup>30,41–45</sup> Kwakwa reported a 20-year-old woman who

have had sex exclusively with a bisexual HIV-infected partner for 2 years prior to being diagnosed with a genetically identical strain of HIV. Reported sexual contact between these two women included oral sex and sharing of sex toys. The newly HIV-infected woman reported that although she never engaged in sex during menses, bleeding during sex had occasionally occurred. The investigators excluded alternative explanations, confirming the patient had never shared toothbrushes or razors with her infected partner, injected drugs, received a blood transfusion nor had had sex with men.

Transmission of syphilis requires only skin-to-skin or mucosal contact which can easily occur in the context of sex between women. In fact, sexual transmission of *T. pallidum*, the causative agent of syphilis, between female partners has been reported.<sup>46</sup> Among WSW who engage in sex with higher risk male sex partners, there may be a higher than usual risk of syphilis acquisition given the recent rise in early infections over the last several years among MSM.<sup>36</sup>

Certain non-sexual risk behaviors including injection drug use (IDU) may be higher among some WSW, and may independently increase risk of HIV acquisition. In one study that included US surveillance for reported AIDS cases from 1980 to 1989, 95% of the 79 women who reported sex with another woman reported current or past IDU.<sup>47</sup> The HIV epidemiologic research study evaluated the sexual behaviors of women who reported prior IDU, had sex with five or more partners in the prior 5 years, had a history of sex with a male sex partner at risk for HIV, or had exchanged sex for drugs or money. In this study, 67 of 871 subjects (8%) have had sex with a woman during the 3.5 years of the prospective follow-up. Most (82%) had a history of IDU. A notable weakness of this study was that information on the HIV status of sex partners was not reported.

## BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is a condition that occurs when the hydrogen peroxide-producing *Lactobacillus* species that characterizes the normal human vagina are replaced by high quantities of commensal anaerobic bacteria. BV is the most common cause of vaginitis among women of reproductive age, and is associated with pelvic inflammatory disease and preterm labor. BV, though mostly considered significant among women in the context of pregnancy, also increases the risk of STI, including HIV acquisition.<sup>48–51</sup>

The prevalence of BV among WSW is high and vaginal colonization with hydrogen peroxide-producing lactobacilli is low relative to that of heterosexual women matched for age and sexual risk behaviors.<sup>52–56</sup> BV prevalence among WSW in several studies has ranged from 24% to 51%, as compared to 21% for heterosexual STD clinic patients and 9–14% for pregnant women. Although BV is not a classic STI in that a specific microbial precipitant has not been identified, Criswell and Gardner successfully transmitted BV from one woman to another by the transfer of vaginal secretions in early studies of “*Haemophilus*

*vaginalis* vaginitis,” a historical term for BV.<sup>57</sup> Moreover, Marrazzo and colleagues, utilizing rep-PCR to characterize vaginal isolates among 30 monogamous (defined within the time frame of the prior 3 months) female sex partners, demonstrated that 23 of these couples shared identical strains of *Lactobacillus*. Finally, other studies have demonstrated that BV is frequently found in both members of monogamous lesbian couples and that BV concordance within couples has been associated with specific sexual behaviors, including shared use of vaginally penetrative sex toys.<sup>58,59</sup> Taken together, these data strongly support a role for sexual exchange of vaginal microbiota in the pathogenesis of BV among WSW.

Although studies have not demonstrated a consistent positive association, the common practice of oral sex among WSW may play a part in the high concordance of BV among both members of monogamous lesbian couples, as certain anaerobic bacteria that may also colonize the oral cavity are newly identified agents associated with this condition.<sup>59–61</sup> More research is needed in this area.

## TRICHOMONIASIS

One case report of exchange of *Trichomonas vaginalis* has been reported among WSW. Both women in a partnership were infected with *Trichomonas vaginalis* that was found to be resistant to metronidazole.<sup>24</sup> Among 708 new patients attending a clinic for lesbians in London, trichomoniasis was detected in 1.3%, including women who reported no prior sex with men.<sup>39</sup> Presumably, efficient exchange of vaginal fluid between female sex partners should facilitate transmission of this common STI, but data in WSW are lacking.

## Preventive Health

In many industrialized countries, one of the most reliable measures of appropriate provision of preventive health among women is cervical cancer screening. Despite the fact that many WSW accurately perceive themselves to be at risk for cervical cancer, several investigators have reported that WSW are less likely to undergo routine Pap smear screening and preventive gynecologic care relative to their exclusively heterosexual counterparts.<sup>3,62–64</sup> Moreover, as demonstrated in qualitative and quantitative research,<sup>65,66</sup> most women who report same-sex behavior do not believe that they are at risk of acquiring STI from their female partners. This may lead to less frequent use of preventive measures (for example, washing sex toys between partners) or infrequent use of barrier methods (including gloves, condoms, dental dams) for STI prevention. Finally, healthcare providers may neglect to obtain a complete sexual history and thus fail to elicit reports from WSW of higher risk behavior that would prompt STI screening and related prevention counseling.<sup>67</sup>

In Australia, WSW have been a target for routine cervical screening campaigns. A study in the state of Victoria among 409 WSW showed that 66% were considered well-screened, 22% were under-screened, and 12% had never had a Pap smear, while 22% have had an abnormal result.<sup>68</sup> These are representative of

population-based screening rates in Victoria; however, younger WSW in the study were found to be under-screened relative to the women over 40 years of age. Also, women who had disclosed their sexual identity to their primary care provider and had never been advised not to have a Pap test by their provider were more likely to be well-screened. Of concern, 9% of WSW had been advised not to have a Pap smear, generally by their primary care providers.

Three studies in the US have reported low rates of Pap smear screening among WSW. In the Seattle Lesbian Health Study, 95% of the respondents believed they should receive Pap smears annually or every 2 years after a normal smear, but 36% provided a reason for not having done so.<sup>27</sup> Reasons most commonly cited were lack of insurance, adverse experience at prior Pap smear screening, and a belief they did not need it because they were not sexually active with men that was often enforced by physicians. Despite high levels of education and income, women with no prior sex with men were less likely to have ever received a pelvic examination, received their first Pap smear at an older age, and had less frequent Pap smears relative to women who reported prior sex with men. The Boston Lesbian Health Project used snowball sampling to query a national sample of 1633 lesbians.<sup>69</sup> Interestingly, while overall screening rates approximated the general population, 39% of respondents younger than 20 years and 16% of those 20–29 years had never had a Pap smear. A study conducted in New York City that utilized a multilingual population-based survey found that WSW were less likely to have had a Pap test in the past 3 years (66% vs. 80%,  $P<0.0001$ ) and a mammogram in the past 2 years (53% vs. 73%,  $P<0.0009$ ) than other women. Women whose sexual identity and sexual behavior were concordant were more likely to have engaged in healthcare screening practices including Pap smears. In other words, WSW who identified as lesbian were more likely to have received timely Pap tests (97% vs. 48%,  $P<0.0001$ ) than those WSW who identified as heterosexual.<sup>70</sup>

Many WSW (53%–72%) do not disclose their sexual behavior to physicians when they seek care, and disclosures may elicit negative reactions.<sup>64</sup> In a survey of 1086 WSW, only 43% with a clear risk factor for HIV perceived themselves to be at risk.<sup>3</sup> Similar assumptions about HPV acquisition from female partners may place these women at risk for delayed detection of cervical cancer by less frequent or no cervical cancer screening. Finally, WSW who do not also have sex with men may not access venues providing hormonal contraception, thus eliminating another routine opportunity for cervical cancer screening to be sought and/or offered.

## Methods to Reduce Risk of STI Acquisition among WSW

The sexual behaviors of WSW allow transmission of cervicovaginal secretions and blood-borne pathogens, as supported by reports of several STI among women who report sex exclusively with women. Several methods may theoretically reduce risk of STI by preventing contact with infected skin, mucous membranes or

secretions; however, none have been directly studied prospectively among WSW. These measures include washing hands between sexual practices and utilizing rectangular latex barriers known as dental dams (used historically by dentists for endodontic procedures). Dental dams can be placed over the vulva during cunnilingus or the anus during anilingus. Some women may choose to use thin pieces of plastic wrap for the same purpose; however, this material may be porous and potentially less protective. Condoms can be used to cover sex toys used for penetrative purposes. If condoms are used, they should be replaced during exchange of toys from one partner to the other. Latex gloves or finger cots can be used during sex that involves digital stimulation, including vaginal and anal penetration.

Despite evidence supporting transmission of STI among WSW, perceptions of risk and practice of safer sex methods is low.<sup>71</sup> In a qualitative study including focus groups among 23 self-identified lesbian and bisexual women between ages 18–29, among a handful who experienced an STI or BV, practice of measures, including washing hands, cleaning sex toys and use of latex barriers is low.<sup>66</sup> This may be due partly to lack of knowledge of STI transmission between women and overall lack of safer sex messaging by primary care providers and public health advocates that target WSW.

## Conclusions

Women having sex with women are at risk for a full range of viral and bacterial STI and associated conditions, with the available evidence strongly supporting the need for attention to studies of transmission of *C. trachomatis*, HSV, HPV, and BV. While there is a paucity of data on most STI in WSW, relatively solid data do speak to the need for adherence to standard screening guidelines for cervical cancer and *C. trachomatis*.

Healthcare providers should apply their skills in sexual risk assessment to all women, including WSW, with particular effort towards inquiring about potential higher risk male partnerships and illicit drug use. Evidence also supports that while WSW may be knowledgeable about safer sex measures, relatively few practice them. Further research on behaviors and mechanisms of disease acquisition and transmission among WSW, including exploration of higher risk partnerships and behaviors, is needed.

# Sexually Transmitted Infections in Transgender Persons

Darren Russell

# 101

Transsexualism is defined in the Diagnostic and Statistical Manual (Version IV) of the American Psychiatric Association as a strong and persistent cross-gender identification with a sense of inappropriateness in the gender role of one's biological sex. The definition specifically excludes any concurrent intersex condition. There must also be clinically apparent distress or impairment in social, occupational, or other important areas of functioning. Definitions are problematic with the condition of transsexualism, however, as there remains considerable debate about the terms that are used, both within medical circles, and within the ranks of transgender folk themselves. It is fair to say that the terms in common usage remain in a state of flux.

A “*transgender*” person is one who dresses as, desires to be, has undergone surgery to become, or identifies as a person of the opposite sex. The terms male-to-female and female-to-male transgender persons are used to refer to individuals who are undergoing or who have undergone a process of gender affirmation. “*Transsexual*” refers to individuals who are born anatomically male or female but who have a profound identification with the sex opposite to that assigned to them at birth. It usually refers to people who wish to make the transition, but for one reason or another are prevented from doing so. “*Intersex*” refers to individuals who were born with reproductive organs and/or sex chromosomes that are not exclusively male or female. These individuals were formally referred to as “hermaphrodites,” or as “children with ambiguous genitalia.”

A “*transvestite*” is somebody who cross-dresses. The term may be used as a synonym for the term “*cross-dresser*,” the latter is generally the preferred term. These terms are different from the term “*transvestic fetishist*,” which describes those who intermittently use clothing of the opposite gender for fetishistic purposes, often accompanied by masturbation or other sexual activities.

Some transgender individuals and organizations argue that transsexualism is not a form of transgenderism, but is in fact a specific type of intersex condition. They argue that transsexualism results when the sexual differentiation or structuring of the brain is not congruent with that individual's chromosomal and genital

sex. Many intersex individuals and organizations, however, take offence at this proposition and vehemently assert that intersex and transsexual conditions are totally separate and have very little in common. Perhaps it is best to realize that our understanding of these conditions is evolving rapidly, and is informed by input from the medical, scientific, sociological, and affected communities, and that our concepts are evolving. In practice, it may be best for healthcare practitioners to use the label that the individual him/herself wishes to use, and to realize that the term that is used today may not be the term that is used tomorrow!

For ease of writing, I shall generally use the terms “transgender” and “transsexual” interchangeably throughout this chapter.

## Prevalence

The proportion of the population who are transgender is small. A 1981 report suggests rates of 1:24,000 males and 1:150,000 for females. More recent data from Europe suggest that 1 in 30,000 adult males and 1 in 100,000 adult females seek sex reassignment surgery. If a broader definition of transgender is used (i.e., one that is not dependant on an individual seeking sex reassignment surgery) then estimates suggest that about 1 in 11,000 males and 1 in 30,400 female individuals are transgender. A study from New Zealand of passport holders, published in 2008, showed the prevalence of male-to-female transgender individuals as 1:3639, and the corresponding figure for female-to-male was 1:22,714.<sup>1</sup> The authors point out that these figures are likely to be underestimates.

## Etiology

The underlying cause of transsexualism is unknown, though numerous theories have been proffered. Most transsexuals recall a feeling of dissatisfaction with their biological gender identity, beginning in early childhood. This implies that transsexualism begins very early in life, and current theories suggest that transsexuals are *born*, and not *made*. Transsexuals are generally entirely normal physically, and characteristically lack concomitant

psychiatric illnesses with the exception of depression. One US study reported that 62% of male-to-female and 55% of female-to-male transgender persons were depressed. Thirty-two percent of both groups had attempted suicide.<sup>2</sup> It is likely that this depression is in large part caused by the discrimination suffered by transgender individuals by a society that is largely antipathetic to those with this condition, or who lie even a little outside accepted cultural gender norms. Rejection by family and friends, difficulties in finding and maintaining employment, and difficulties in forming intimate relationships, are all potent factors that may contribute to depression. Genital and other forms of body mutilation may also occur—and may even include auto-castration—especially in those individuals who are denied the opportunity to undergo sex reassignment.<sup>3–5</sup>

## Differential Diagnosis

The diagnosis of transgenderism is usually quite straightforward. By the time an individual has summoned the courage to attend a healthcare professional, they have generally been aware of their condition for many years and have already gained information about transgenderism and its possible treatments. More frequently these days, the Internet is an important source of information and support for transgender individuals. There are several conditions, however, that, on occasion, may be confused with transgenderism. Intersex conditions, cross-dressing, and transvestic fetishism have been mentioned above, and, rarely, *schizophrenia* may present as gender confusion, though the associated thought disorder and other typical features of schizophrenia generally make this condition readily identifiable from transgenderism. It must be remembered, however, that transgenderism may rarely coexist with schizophrenia.

## Treatment

There are increasing concerns with the use of the medical paradigm and the concept of “treatment” when referring to a condition that may merely represent one aspect of the spectrum of the human condition. It was only in 1973 that the diagnosis of homosexuality was removed from the list of mental illnesses in the US, and even more recently in other countries such as China. Likewise, it may eventuate that transgender individuals in the future will be regarded as merely requiring hormone and surgical therapy to return them to their rightful states, and not as a treatment for a psychiatric illness. The management of transgender individuals remains complex and experience-driven, though the World Professional Association for Transgender Health has developed Standards of Care. In most western countries, the emphasis is on psychiatric or psychological assessment and management; in Latin America, however, the emphasis is on the ability to “pass” as the chosen sex, and in Thailand the emphasis is generally placed on cross-living experience.

Treatment typically involves the provision of assessment and counseling initially, followed by the institution of hormonal

therapies (estrogen—and sometimes anti-androgens—in males-to-females, and testosterone in females-to-males). As stated above, the assessment process is generally straightforward in most individuals, though on occasion it can be problematic. Psychiatrists, psychologists, and/or physicians with an interest in transsexualism may carry out the assessment. It may require several interviews over several months and may also necessitate the so-called “real-life experience” when the person lives full-time as their chosen sex. Nowadays, this is commonly done in combination with hormone therapy, though some healthcare professionals prefer to wait some months after the initial interview before commencing such treatments.

Sex hormones exert a negative feedback on the hypothalamus and pituitary gland. Levels of gonadotropin-releasing hormone, luteinizing hormone and follicle stimulating hormone are all regulated or suppressed by levels of endogenous sex hormones. Hormone therapy aims to reduce these levels, leading to a reduction in endogenous estradiol or testosterone production. Furthermore, exogenous estrogen will induce feminization, and exogenous testosterone will induce virilization.

Transgender individuals may or may not choose to undergo surgical genital reassignment (sometimes referred to as “genital realignment”), and this will also be contingent on the availability of surgical expertise, and on the financial resources to pay for these procedures. There are a variety of surgical procedures available, and these are being continually refined. The aim of surgery is to enable the transgender individual to more fully live as their chosen sex, and to function well sexually. In most cases this is now possible. Male-to-female genital surgery is technically simpler than female-to-male surgery, and is generally more successful. The vast majority of post-operative individuals report an overall improvement in their lives and are happy with the decision to have genital surgery.<sup>6</sup>

A Belgian study of 55 transsexuals (32 female-to-male and 23 male-to-female), published in 2005, concluded that after surgery the person's expectations were met at an emotional and social level, but less so at a physical and sexual level. Eighty percent of the participations reported improvement of their sexuality, however. The females-to-males masturbated significantly more frequently than the males-to-females. The majority of participants reported a change in orgasmic feeling, toward more powerful and shorter for females-to-males, and more intense, smoother, and longer in the female-to-male group.<sup>7</sup>

A small minority, however, are greatly dissatisfied post-surgery and regret the decision to undergo it. This reinforces the need for expert assessment initially but points to the fact that it is not possible to determine with perfect accuracy who will, and who will not, be satisfied post-surgery.

## STIs in Transgender Persons

It has been estimated that 60% of transgender people have been infected with some type of STI. Recently, more data have been published on the prevalence of various STIs in transgender

populations. Most healthcare providers still lack information about transgender health issues and in this particular population.

A disproportionate number of transgender individuals find employment in the sex industry because of discrimination in the workplace and subsequent financial hardship. For some transgender individuals in some countries this remains the only means of earning enough money to survive, and to afford hormonal and surgical treatments. Jobs may be lost during the transition process, or after transition it may be difficult for transgender persons to find work if they do not “pass” as their reassigned sex. Because of stigmatization even within the sex industry, transgender persons are more likely to engage in unprotected intercourse.<sup>2</sup> There may also be a financial incentive to engage in risky activities if this means that the person can earn more money to put toward the often-high cost of surgery.

Intercourse may be oral, anal, or neo-vaginal in the post-operative person. In pre-operative male-to-female individuals, and in post-operative individuals with a short vaginal barrel, thigh intercourse (sometimes referred to as “cuissage”) may be practiced instead of vaginal intercourse. Pre-operative female-to-male individuals may sometimes engage in receptive penile-vaginal intercourse, and this may be with heterosexual, bisexual, or homosexual males. Pregnancies would be very unlikely to occur in those individuals on adequate testosterone therapy.

A number of American studies have looked at the prevalence of STIs (including HIV) among transgender persons. A study in Chicago found that 46% of individuals had been forced to have sex, 14% were HIV-positive, 22% had been diagnosed with an STI, and 48% of male-to-female and 85% of female-to-male transgender individuals had had sex without a latex barrier.<sup>2</sup> A retrospective study of the health status of transgender individuals in the US reported a 35% prevalence of HIV for male-to-female transgender individuals. A cross-sectional study from Rome, Italy, assessed the prevalence and incidence of HIV infection in foreign transsexual sex workers and found an overall HIV prevalence of 38.2%, with an observed HIV seroconversion rate of 4.1 per 100 person-years.<sup>8</sup> These HIV prevalences seem inordinately high, but the prevalence in a given population will, of course, vary depending on the prevalence in the general community and on the risk behaviors for the particular transgender population.

A US study published in 1999<sup>9</sup> showed that transsexual inmates were 13.7 times more likely to have a main sex partner while in prison. Furthermore, they were 5.8 times more likely than non-transsexuals to have more than one sex partner while in prison. Given that rates of HIV are nearly always higher in prison populations than in the non-incarcerated population, and that injecting drug use is common, these data give cause for real concern. The provision of condoms and materials for safe injecting use is rare in the world’s prisons and so the potential for the transmission of blood-borne viruses is high. Sexual assault is also a significant risk for transsexual inmates in prisons.

A study from Sydney, Australia, looked at transgender people attending a sexual health service over a 16-year period<sup>10</sup> and of the 40 patients who were identified, 17 (43%) had a history of

sex work, 16 (40%) had injected drugs, and 14 (35%) had had unprotected anal or vaginal sex in the previous 3 months. Twenty (50%) patients had histories of an STI, including three (7.5%) who were HIV-positive. Genital warts and Chlamydia were the most common diagnoses during the study period.

In southern India, a study published in 2008 showed high HIV prevalences among *bijra* (intersex—physiological males who have feminine gender identity, women’s clothing and other feminine gender roles) (18.1%), bisexuals (15.9%), *kothis* (passive receptor) (13.5%), double-deckers (10.5%), and *panthis* (active inserter) (7.6%).<sup>11</sup> Syphilis prevalence was also high among *kothis* and *bijras* (15.8 and 13.6%, respectively).

A recently published study from Mumbai, India, looked at sexual behavior and STIs among 75 male sex workers (24 men and 51 transgender).<sup>12</sup> The HIV prevalence in the group was 33%, but was significantly lower in men (17%) compared with transgender participants (41%). The STI prevalence overall was 60% with syphilis once again being the most common STI apart from HIV (28% overall).

There remains a dearth of data regarding the risk of many other STIs in transgender individuals in many countries. Perhaps the best that can be said is that the risks will vary according to the disease prevalences in the general population, the risk behaviors of transgender individuals, and the ability of such individuals to access healthcare and treatments. In general, though, as for all STIs, marginalized groups are often at the highest risk, and transgender individuals are some of the most marginalized members of society.

## Post-Surgery STIs

There is even less data regarding the risk of STIs in post genital surgery transgender individuals. Following surgery, there are several reasons to believe that the risk of some STIs will be decreased. Access to bacterial STIs such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in the adult biological female is often via the cervix uteri, and post-surgery male-to-female transsexuals lack a cervix. They have, instead, a neo-vagina composed of inverted penile skin (with or without a distal colon loop), and a surgically made urethral meatus. Infection of these tissues with the gonococcus and Chlamydia seems to be very unusual.

I have observed, however, the presence of genital warts and genital herpes in the neo-vagina, but cannot comment on the prevalence of these conditions. It would make sense, though, that these viruses could cause infection in the neo-vaginal tissues, as in the male penile skin. Likewise, syphilis and chancroid, which can cause ulceration in penile epithelium, would be able to cause ulcers in the neo-vagina. I have not observed these conditions, however, in post-surgical transgender persons. There would also be a theoretical reason to believe that post-surgery there would be less risk of the acquisition of HIV infection via receptive penile-vaginal intercourse. Without a cervix (through which most HIV infections in biological women are probably acquired), the male-to-female transgender woman may be at less risk of HIV infection.

Complicating the picture, though, is the presence of traumatic or other ulcers following surgery. The need for frequent neo-vaginal dilatation to prevent the closure of the vaginal barrel can induce traumatic ulceration, or even disruption of the distal vaginal cuff. Similarly, penile-vaginal intercourse can result in trauma, especially as the neo-vagina may be too short and/or narrow for vigorous intercourse, and is not self-lubricating like a biological vagina. This could then allow the ingress or egress of bacterial or viral particles across abraded or ulcerated surfaces.

Where the neo-vagina is of sufficient diameter and length for adequate penile intercourse, traumatic ulceration is less likely to occur. If a colon loop has been surgically added to the distal vaginal cuff, ongoing dilatation is less necessary, and lubrication occurs via normal colonic mucous production. Colonic mucosa, however, *may* be intrinsically less resistant to some sexually transmitted infections than penile squamous epithelium.

It must always be kept in mind that transsexuals, whether male-to-female or female-to-male, may be at risk of STIs via oral or anal sex, and may also be at risk of blood-borne viruses via injecting drug use.

## Conclusion

Transgender individuals have been relatively infrequently studied with respect to STIs, though they may be at higher risk through a combination of various biological reasons and sociological reasons such as stigma, discrimination, and lack of access to healthcare. It is important that healthcare professionals take these factors into consideration when dealing with transgender individuals. Further studies into transgender healthcare issues remain a high priority.

# Sexual Abuse in Children

Savita Malhotra • Nitin Gupta • Anindya Banerjee

# 102

## Introduction

Child sexual abuse (CSA) has been an extremely serious, socially disruptive, psychologically devastating, and medically damaging form of trauma that historically has generated much emotional reactions ranging from denial and rage to malice, exclusion, and victimization of the sufferer in the societies.

The phenomenon of CSA has been well-recognized since as early as the 19th century but it is only recently that there is professional acceptance of its reality. Freud<sup>1</sup> in his lecture on “the etiology of hysteria” had proposed a link between CSA and hysteria. Though in psychiatric research, there were sporadic reports of CSA earlier, a dramatic increase has been recorded since early 1980s. CSA has been a subject of intensive research and clinical study by professionals in the fields of mental health as well as in medical and social sciences. Nevertheless, the entire subject still continues to be shrouded in mystery. It is a complex problem that involves several dimensions ranging from medical, social, psychological, legal, ethical, and moral, in its conceptualizations. Further, there is considerable lack of consensus and clarity in most areas related to the subject that still continues. Since the subject of CSA has been a taboo, societies have often reacted with a so called “ostrich psychology” by either closing their eyes to its presence or by dumping it as a myth or an imagination of the child. Often children reporting CSA were not heard, not taken seriously, shunned, and at times considered to be imagining things that were impossible. Under the circumstances, children were left with no one to confide in and they lived their lives under persistent trauma of abuse. This further led to reluctance of the affected individuals to share their traumatic/painful experiences with the medical health professionals, thus hindering research and further understanding of the phenomenon.

It has also been seen that sexual abuse in children occurs along with other forms of maltreatment, that is, physical abuse, emotional abuse, and neglect,<sup>2,3</sup> making the actual experience of children very complicated, presenting challenges for the clinicians and researchers. CSA contributes to child mortality and morbidity with long standing effects on mental health, alcohol,

and drug abuse, suicide, criminality, risky sexual behavior, eating disorders, and so on that persists well into adulthood. Considering the seriousness of consequences and very high prevalence, the problem of CSA warrants preventive and therapeutic intervention from the very early childhood.

## Definition and Concept

Numerous definitions have been provided for CSA. However, most of these have been fraught with conceptual problems. Any definition of CSA should encompass the following components viz. what is meant by “sexual,” what is the age or developmental level of the participants, and what should be called as “abuse.”<sup>4</sup> For example, Schecter et al.<sup>5</sup> defined CSA “as the involvement of dependent, developmentally immature children and adolescents in sexual activities they do not truly comprehend, to which they are unable to give informed consent, or that violate the social taboo of family roles.” This definition does not clarify about the age, as developmentally immature can be at varying ages depending upon the achievement of puberty; sexual activities can range from use of sexual language to the extreme of sexual intercourse—what is to be termed as amounting to a sexual activity becomes difficult; and indulging in sexual activity can be termed as abuse not only by absence of informed consent or violation of social taboos, but also if it is done for the purpose of sexual satisfaction of the perpetrator. Hence, one can see that the above definition is far from satisfactory. Finkelhor<sup>6</sup> defined “sexual victimization” as, “sexual encounters of children under age thirteen with persons at least five years older than themselves, and encounters of children thirteen to sixteen with persons at least ten years older.” This definition is highly unsatisfactory in terms of not only absence of the concept of “sexual” and “abuse,” but also by the age criteria used. What if the child of age 12 years is subjected to sexual victimization by an adolescent of sixteen years? What if an adolescent girl of 14 years is subjected to sexual assault by a male of twenty years? Hence, despite numerous definitions and conceptual problems, comprehensiveness could not be achieved satisfactorily.

However, the most comprehensive definition can be the one by the Standing Committee on Sexually Abused Children,<sup>7</sup> which states—“Any child below the age of consent may be deemed to have been sexually abused when a sexually mature person has, by design or by neglect of their usual societal or specific responsibilities in relation to the child, engaged or permitted the engagement of that child in any activity of a sexual nature which is intended to lead to the sexual gratification of the sexual mature person”. This definition pertains whether or not this activity involves explicit coercion by any means, whether or not it involves genital or physical contact, whether or not initiated by the child, and whether or not there is discernable harmful outcome in the short term. Also, by this definition, sexual activity between two sexually immature persons (e.g., children) cannot be termed CSA.

Despite numerous conceptual difficulties, if one tries to understand the concept of CSA (and define it), then a practical and broad definition could be—sexual behavior between a child and an adult or between two children when one of whom is significantly older or uses coercion. The perpetrator and the victim may be of the same or opposite sex. The sexual behaviors include touching breasts, buttocks, and genitals (whether the victim is dressed or undressed); exhibitionism, fellatio, cunnilingus, and penetration of the vagina or anus with sexual organs or with objects. Pornographic photography is usually included.

Several forms of sexual behaviors can be seen in school/preschool age children that can range from developmentally expected normal to abusive behavior.<sup>8</sup> Thus, it is important to consider developmental factors while labeling CSA. CSA has to be distinguished from sexual play, which has been defined as sexual activities by preadolescent children of same or opposite sex, separated by no more than 4 years of age, in which there has been no force or coercion.<sup>9</sup>

## Epidemiology

It has been reported that the prevalence of CSA has assumed epidemic proportion affecting children and communities worldwide.<sup>10</sup> CSA has been described as an insidious, persistent, and serious problem that affects 2–62% of women and 3–16% of men as victims depending upon the population studied and the definition used.<sup>11</sup> The true prevalence of CSA is difficult to ascertain due to numerous factors. Broadly speaking, there are two sources of information: (a) data from studies on children who have been sexually abused referred to various agencies like police, social services, and doctors. (b) studies on adult populations exploring into their sexual experiences as children.

Both sources are associated with certain limitations. Official figures from records of medical, legal or social agencies are unreliable as the reporting of the problem is inadequate. In addition, there is generally a poor response rate or lack of cooperation from these agencies, and there is marked restriction of cases to only those that actually come to such sources. The latter source of information makes researchers to rely on questionnaires, inventories

and interviews. These methods of assessment are associated with certain problems viz. reliability of the information provided by the persons, difficulty in being able to corroborate the information from any other source, bias in the information due to the long time interval between the “incident” and the interview, and issues related to the information provided due to its highly emotional and sensitive nature. A problem common to both approaches has been that the definition of CSA has kept on changing leading to difficulty in comparing the data. Apart from the difficulties with regard to definition of CSA, the differences in the data gathering techniques (nature of instruments, who has applied them etc.) and heterogeneity in the age of sample also contributes to the large variability in incidence and prevalence rates of CSA. Laserman<sup>12</sup> has reported that 15–25% of general female population is estimated to have a lifetime history of sexual abuse.

Data from specific agencies’ has shown that there was a sharp increase in cases of CSA during the 1980s<sup>4</sup>; especially in those reported from the UK. Correspondingly, in the USA, the number of suspected and established cases of CSA grew at a rate of greater than 10% per year during the 1980s.<sup>13</sup>

Data from adult population have also shown that CSA is a common phenomenon. Prevalence rates of 10%<sup>14</sup>–59%<sup>15</sup> were reported in the UK-based studies (which were supposed to be representative of the general population) done on the population sample sizes varying from 206 to 1244 persons. Studies from Australia and New Zealand have shown prevalence rate of 22%<sup>16</sup> and 31.9%,<sup>17</sup> respectively. Another study from Australia suggested higher prevalence rates of 33.7% for contact CSA and 42.3% if non-contact forms of CSA were included.<sup>18</sup> Rates from the US have been higher, that is, 38%<sup>19</sup>–65%<sup>20</sup>; though derived from smaller samples. Recent prevalence from US government is a more modest 10.1%; 1.7/1000 girls, and 0.4/1000 boys.<sup>21</sup> Reported rates of CSA in different parts of Europe have varied from 3 to 36 % in girls; 1–15% boys of younger than 16 years.<sup>22</sup>

Finkelhor<sup>23</sup> reviewed 19 retrospective surveys with regard to their experience of unwanted sexual contact as minors, and found a prevalence rate of 1–16% in men and 2–45% in women; prevalence of genital penetration being 1.5% in men and 5% in women. In a review,<sup>24</sup> it was mentioned that cases of CSA in the US rose sharply between 1977 and 1988, leveled off, and registered a decline thereafter. Currently, about 200,000 children with suspected sexual abuse are available to the National Committee to prevent child abuse in US.<sup>25</sup> Between 5 and 10% of girls and up to 5% of boys are exposed to penetrative life sexual abuse and up to three times this number are exposed to any type of sexual abuse.<sup>26</sup>

Data has consistently shown that both boys and girls can suffer from CSA; but the rates are lower (between one-fifth to two-thirds) in boys as compared to girls. Part of it is the problem of reporting, as this could be attributed to reasons of socialized feelings and fear of being called homosexuals. The commonest age range is 8–14 years, though extremes can be present.<sup>27</sup>

CSA cuts across all ethnic groups but American studies have shown it to be probably more common and severe in

Afro-Americans.<sup>28,29</sup> The social class distribution suggests a predominance of lower and middle social class groups. It has been argued that the phenomenon is not uncommon among the higher social class; it is just under-reported.<sup>4,29</sup>

Epidemiological data that is now available suggest that the phenomenon of CSA is prevalent in India. The World Health Organization puts the prevalence figure at around 10%. A study conducted in Mumbai in 1985 reported that 30% of female adults and 10% of male adults had a history of CSA.<sup>30</sup> Nambiar<sup>31</sup> reported that 54% of the rape victims in New Delhi were below 15 years of age. Prevalence rates from Bangalore have been around 15%.<sup>32</sup> Additionally, a significant percentage had been abused by either family members or relatives<sup>30,33</sup>; and differing methods of abuse have been adopted by the perpetrators.<sup>30</sup>

The largest national level survey conducted by the Ministry of Women and Child Development, Government of India, released its data recently.<sup>34</sup> The sample consisted of 17,220 children and adolescents in the age range of 5–18 years selected by a multi-stage purposive sampling design. This is the most authoritative report on child abuse in India. This initiative is particularly laudable as it brought this sensitive issue out of the closet into the public domain in India. The survey revealed that two of every three children were physically abused, more commonly in boys and most often by parents. 53.22% children reported having faced one or more forms of sexual abuse, of which 21.9 % faced serious forms of sexual abuse like sexual assault, making the child fondle private parts, exposing or photographing the private parts of the child. Children on street, children at work, and children in institutional care reported the highest incidence of sexual assault. In half of the cases abusers were persons known to the child or in a position of trust and responsibility and most children did not report the matter to anyone.

During the last decade, the concept of “internet sex offenders” has gained ground, where the victim is targeted through the internet, which is a form of non-contact CSA. A comparison of internet sex offenders with actual sexual molesters showed that there were marked similarities in socio-affective traits and childhood physical abuse.<sup>35</sup>

The rates of CSA do appear to be very high, but need to be interpreted in the light of the methodological shortcomings mentioned previously. Additionally, another important aspect to realize is that the rates are reported to be higher in persons with psychiatric illnesses than in the general population. This assumes importance in the context of psychological aftermath of CSA (discussed later).

## Etiology

To some extent, CSA can be viewed as a social phenomenon, which is linked to general attitudes and practices towards children, and ways in which social relationships are organized and regulated in a particular society.<sup>4</sup> Wherever permissiveness is present, the chances of CSA increase due to increased frequency and intimacy of contact between the adult and the child coupled with decreased

vigil by the caretakers of the child. But, this does not imply that CSA is less and not related to the conservative attitude of the society. Untold or hidden cases may be more frequent in such a conservative society. However, additional and key roles are played by the psychological and “interpersonal network” factors. The ecological model views child maltreatment as a social-psychological phenomenon where factors within the individual, the family, the community, and the culture are embedded.

Finkelhor<sup>6</sup> suggested a “four preconditions” model of CSA that distinguishes between the “motivation to sexually abuse” and three “inhibiting” factors that have to be overcome before abuse actually occurs. The factors under “motivation” basically refer to the abuser’s sexuality. The “inhibiting” factors are (a) internal (e.g., moral values of the abuser/adult), (b) external (e.g., supervision of the child by others), and (c) the child’s own resistance toward the advances of the adult. When these inhibitions are overcome, CSA can occur. Certain occasions where the “inhibitions” are overcome (or get overpowered) could be—use of alcohol by the adult, physical or psychological absence or illness of the child’s mother, emotional insecurity or isolation being experienced by the child etc.<sup>4,6</sup> This psychological model links masculine sexuality and CSA, where the abuser is held responsible for the occurrence of the specific act of abuse.

Another influential theory was the “Family Systems Theory.”<sup>36,37</sup> This theory proposes that the basic problem of the father-daughter incestuous relationship is a dysfunctional family arrangement in which the parents suffer from an “emotional-sexual” conflict (i.e., confusion between conflicts on emotional and sexual levels) that leads to intergenerational confusions related to sexuality. For example, when the child comes to the parent(s) seeking emotional relief/care, he/she gets a sexual response. Two types of family pathology serve to sustain this form of incest.

- (a) Conflict avoidance: Individuals in the family are too insecure to cope up with the event and no one acknowledges what is happening.
- (b) Conflict regulation: Disorganized and argumentative members are open about incest with one another, but hide it from the outside world.

Whatever may be the type of family pathology, not discussing about the conflict or trying to hide the issue/problem from the outside world only tends to worsen the situation, increase chances of re-occurrence, and lead to development of adverse psychological reactions in the child. A recent study<sup>38</sup> highlights the serious issue of blame associated with CSA and how internalization of this blame can cause symptoms in the child. Despite these theories, one should try to understand that both the psychological and family models have their criticisms. However, they do tend to provide a theoretical framework in which the setting and perpetuation of CSA can occur.

It is pertinent to mention certain selected risk factors associated with CSA: maternal youth, parental death, presence of stepfather, harsh punitive tactics, maternal sociopathy, unwanted pregnancy, female gender, older children, and parental h/o childhood maltreatment.<sup>39</sup>

## Sexual Offenders/Abusers

It is equally important to try characterize and understand the persons who indulge in abusing children sexually, that is, the sexual offenders/abusers.

Considerable research is available regarding sexual offenders or pedophiles (a person at least 16 years of age and who indulges in sexual activity with children under 13 years of age).<sup>40</sup> Pedophiles can be of any age. Varying, but high degree of psychological disturbances and psychiatric illnesses have been found in the pedophiles.<sup>41,42</sup> Some authors have questioned the utility of the diagnosis of pedophilia, given that the criteria for specifying who is and who is not a pedophile are not strongly related to one another. They suggest that child molester may be a better term.<sup>43</sup> The adult sex offenders have a high prevalence of personality disorders.<sup>44</sup> Numerous predisposing factors viz. familial, social, academic, and developmental have been implicated for the initiation or perpetuation of sexual offence by these persons.<sup>45–48</sup> Juveniles who commit sexual offenses are a heterogeneous diverse population.<sup>49,50</sup>

Males have most commonly been linked with CSA. However, a most recent report from ChildLine (UK) suggest that the number of children reporting CSA by women has more than doubled in the last 5 years; nearly 25% reporting females to be the offender (<http://news.bbc.co.uk/1/hi/education/8347589.stm>; dated 9 November 2009).

In a review article, presenting meta-analysis of studies on risk indicators for perpetration of CSA between 1990–2003 reported that sex offenders against children were by large no different from sex offenders against adults but they were different from non-offenders on several family factors, behavioral problems, social deficits, sexual problems, beliefs and attitudes.<sup>51</sup> There have been some shocking instances of CSA within the Catholic Church, an issue that has been reviewed and reported<sup>52</sup> with the argument that the priests guilty of CSA are child predators who differ little from other child predators.

## Psychopathology/ Psychological Consequences

Trauma of CSA leads to serious, persistent, and long standing consequences that could persist through adulthood. Though children with CSA manifest psychiatric problems, no specific syndrome has been related to CSA.<sup>53</sup> A host of risk factors leading to psychological problems in CSA have been reported, that is, family-related, abuse related, individual vulnerability, response of others to the event, etc.<sup>54–57</sup> However, every person with a history of sexual abuse does not develop psychiatric symptoms or impairment in functioning. CSA is linked with certain psychological sequelae both during childhood and adulthood. During childhood, emotional disturbances,<sup>55</sup> sexually inappropriate behaviors,<sup>58</sup> suicidal behavior<sup>59</sup> and anxiety problems,<sup>60</sup> and somatoform complaints<sup>61</sup> are some of the common and intensely disabling consequences. A recent study reported frequent association between ADHD symptoms and dissociative disorder in abused children.<sup>62</sup>

From India, surprisingly, the literature on the psychological impact, outcome, and treatment of patients with CSA is meager. Patel et al.<sup>63</sup> had reported on the psychological aspects of 35 children with CSA in a remand home in Mumbai, and found history of psychological problems in 71% of the parents of these children. Additionally, 57% of these children were suffering from some psychiatric illness; commonest being depression.

In a meta-analysis to study association between CSA and self-injurious behavior, it was found that the theory that CSA has central/causal role in self injurious behavior was not supported by evidence. However, the modest association between the two was attributed to their correlation with the same psychiatric risk factors.<sup>64</sup> There is also a greater risk of physical disorders such as headaches, gastrointestinal disorders, somatic symptoms, and panic symptoms in these children.<sup>65</sup>

Although it was mentioned earlier that some children do not manifest with any psychiatric illnesses in the period immediately following sexual abuse, yet this does not support the notion that all is well with these children.

Long-term or adulthood outcome is more complex which can be permanent and even life threatening. Ramifications of the effects of CSA are seen well into the adolescence and adulthood where the presence of psychiatric illnesses is directly or indirectly linked to sexual abuse in the childhood. Adults can manifest with varied emotional and psychological reactions, including socialization, personality disorders, substance abuse,<sup>66</sup> and depression<sup>54,67</sup>; experience adverse social consequences<sup>68</sup>; sexual problems; parenting difficulties<sup>69</sup>; and are at risk for HIV.<sup>70</sup> Research has shown relatively consistent association between CSA and sexual risk behavior, such as sex trading, sexual promiscuity, and early age of first sexual intercourse, but whether this relationship is causal, is not fully understood as yet.<sup>71</sup>

1. There is scant literature on CSA among boys, but psychological consequences such as anxiety, denial, dissociation, and self mutilation are common. Boys may cope with abuse by becoming the angry avenger, the passive victim, a daredevil, or a conformist.<sup>72</sup> In adult populations with psychosis, impact of CSA has been linked with the onset of schizophrenia<sup>73</sup> and also with high level of anxiety among people with schizophrenia.<sup>74</sup> Other consequences of CSA, such as emotional distress, depression, anxiety, dissociation, and Posttraumatic stress disorder, have been found to be linked with mediational factors in the form of self blame, shame, and avoidant behavior. Further, emotional distress appears to mediate link between CSA and alcohol abuse or re-victimization.<sup>75</sup> Thus, there is need to incorporate several methodologies to understand the psycho pathogenesis. Ball et al.,<sup>76</sup> while reviewing the evidence for a causal link between borderline and childhood trauma, concluded in support of a causal relationship particularly in a multi factorial etiological model.

## Physical Consequences

Numerous studies have been carried out to determine the prevalence and relationship of CSA and physical health disorders.<sup>12</sup> CSA has been associated with worse functional disability, more physical symptoms, more physician-coded medical diagnosis, increased emergency room visits and healthcare costs,<sup>77</sup> and increased risk of more behavioral health-risk factors.<sup>78</sup>

Additionally, there is consistent greater association with abdominal pain and gastrointestinal symptoms, pelvic pain and gynecological disturbances, headaches, and physical symptoms of anxiety.<sup>12</sup>

There is evidence to suggest that more invasive sexual abuse, multiple incidents, and longer duration of abuse are associated with worse physical health status.<sup>12,79,80</sup>

## SEXUALLY TRANSMITTED INFECTIONS

A recent study focusing on urban youth suggests that urban adolescents who are abused are at higher risk to develop underage pregnancy, sexually transmitted infections and alcohol/drug abuse compared to non-victimized peers.<sup>81</sup>

The prevalence of sexually transmitted infections in children with CSA ranges from 2 to 7% in girls and from 0.5 to 1% in boys.<sup>82</sup> A recent review reported rates of 1–5% in prepubertal children.<sup>83</sup> The most prevalent STIs are chlamydial infections, genital warts, and gonorrhoea,<sup>84</sup> whereas HIV infection and syphilis are rare.<sup>24</sup>

## HIV Infection

HIV transmission due to CSA has been a topic of research since early 1990s. It is important to remember here that intercourse, as a part of CSA, is essential for its occurrence. Wide variation in the prevalence rate has been reported, that is, 0.3<sup>85</sup>–68%,<sup>86</sup> but the sample size and methodology applied have varied considerably. In fact, certain researchers have shown that CSA did not manifest later on with HIV positivity.<sup>84,87</sup>

The risk of transmission of HIV from a single event of unprotected receptive vaginal intercourse when the perpetrator is infected with HIV is 0.0001–0.003 and the risk of unprotected receptive anal intercourse is 0.005–0.032.<sup>88</sup> During evaluation of a person who has had a potential exposure to HIV and, therefore, may need post exposure prophylaxis, considerations include duration of time that has passed since the potential exposure; likelihood that the perpetrator is exposed to HIV; type of exposure; potential side effects from the therapy; and the patient's adherence to the therapy regimen. HIV post exposure prophylaxis should be initiated as soon as possible after the potential exposure and before 72 hours of the exposure.

## Genital Warts and Human Papilloma Virus (HPV) Infection

A complex interplay between HPV infection, genital warts, and CSA is seen viz. exposure to HPV infection is not necessary

to manifest with warts<sup>89</sup> and there can be a prolonged latency period of up to 5 months for the manifestation of the warts.<sup>90</sup> Studies have shown the presence of HPV DNA, but not genital warts, in children with sexual abuse.<sup>91,92</sup> HPA DNA positivity has been reported in up to 33% of children with sexual abuse.<sup>93</sup> On the other hand, condyloma (or warts) has been seen in 1.8% of children with sexual abuse.<sup>93</sup> It is pertinent to mention here that presence of genital warts in children aged 2–3 years is not always suggestive of CSA.<sup>24</sup> Sexual abuse must be considered in children with anogenital, laryngeal, and oral HPV, but nonsexual transmission like vertical transmission from parents, heteroinoculation from caregivers, and autoinoculation must be considered as well. At times, this differentiation may be extremely difficult, owing to factors like the long incubation period between acquisition of HPV and the development of warts, an unknown incubation period upper limit, the myriad presentation of lesions, and the propensity of lesions to spontaneously remit.<sup>83</sup>

Among HPV DNA, subtypes 6 and 11 have been reported more frequently than subtypes 2 and 3<sup>93</sup> in children with sexual abuse. However, caution should be exercised when attempting to identify HPV DNA in an adult.

## Others

In 33% of children with sexual abuse, abnormal cytology in the form of squamous metaplasia has been reported.<sup>93</sup>

## Arriving at a Diagnosis

Children often do not disclose experiences of abuse for months and years. Caregivers must be sensitive to and cognizant of the medical and behavioral indicators of abuse. Various guidelines have been framed for assessment of children with probable sexual abuse. One of the most comprehensively outlined recent guidance is from the UK by NICE ([www.nice.org.uk/CG89fullguidance](http://www.nice.org.uk/CG89fullguidance)).<sup>94</sup> This guidance has been developed not only to raise awareness but also to help non-specialist healthcare professionals to identify children who are being abused.<sup>94</sup> The NICE guidance lists five points of good practice, that is, to listen and observe, to seek an explanation, recording of information, consider/suspect or exclude maltreatment, maintain appropriate, and complete record/documentation.<sup>94</sup>

Assessments are generally multidisciplinary/multi-specialty, and there is a need for participation of specialized professionals (psychologists, psychiatrists, psychoanalysts, and pediatricians) and relevant others (general practitioners, social worker, health visitor, district nurses, etc.). The non-specialist healthcare professionals tend to act as gatekeepers and source of raising the initial index of suspicion towards the possibility of CSA. If they have a strong index of suspicion, based on their assessment, they should alert the relevant specialists, social services and police for a further detailed assessment and in order to ensure protection of the identified victim.

However, whatever guideline is followed, the basic underlying principle is of elicitation of a comprehensive history and

psychological-cum-physical examination. At the same time, caution needs to be exercised by the examining clinicians. This is especially related to having awareness of the normative sexual behaviors of children. Normal sexual play activities between children should not be taken as CSA at face value. Additionally, to know as to what degree is the sexual behavior of the children with sexual abuse above the expected, a baseline understanding is important.

Along with the above-mentioned issues, the disclosure of CSA is itself compounded by problems of over reporting and under reporting. Over reporting tends to occur if the child is suggestible or if there is evidence/possibility of tangible benefits to the child.<sup>95</sup> Under-reporting can be due to various factors viz. presence of feelings of shame, guilt or fear in the child, wish of the child to protect the abuser(s) with whom a consistent relationship is there,<sup>96</sup> reluctance or avoidance in discussing unpleasant memories related to CSA,<sup>97</sup> fear of having to face negative responses, that is, disbelief, denial, or outright rejection,<sup>98</sup> presence of periods of amnesia (memory loss) for such traumatic events during childhood,<sup>99</sup> and the child tending not to label events of sexual abuse as “abusive.”<sup>100</sup> Additionally, the interview should be conducted with caution, according to the reaction and approach of each health professional, avoiding the victim from repeating his/her story to different professionals as that may intensify the suffering.<sup>101</sup>

Hence, assessment for evidence of possible CSA is not simplistic. It does require a considerable degree of experience, expertise, and tact on the part of clinicians to carry out the same. Pediatricians are generally the first health professional from whom advise/assessment is sought in cases of the possibility of CSA.<sup>101</sup> Although they carry considerable expertise in conducting assessments, concerns have been raised around the inability of some pediatricians to distinguish between normal and abnormal characteristics of the genitalia; especially female genitalia.<sup>102</sup>

Though there are numerous assessment protocols, but probably the most comprehensive assessment schedule for forensic evaluation of children and adolescents with sexual abuse is that outlined by The American Academy of Child and Adolescent Psychiatry. A brief overview of the assessment parameters is highlighted.

## INTERVIEW TECHNIQUES

Several key issues are faced by professionals addressing/evaluating CSA. Therefore, it is imperative that one tries to evaluate them. Some key issues are- trying to find out what happened, evaluation for emotional disorders, considering other possible explanations for these emotional disorders, being aware of related developmental issues, avoidance of bias related to outcome (due to one's preconceptions), being sensitive in perusal, being supportive to family members, and maintenance of accurate records.

The Step-wise interview<sup>103</sup> is one systematic way of assessment. It has, however, not been empirically tested. Its components are: rapport building (i.e., establishing a working therapeutic

relationship), describing any two specific events (i.e., asking non leading, open-ended questions), telling the truth, introducing the topic of concern, free narrative (after the topic of abuse has been introduced), general questions, specific questions (if necessary), interview aids (if necessary), concluding the interview.

Additionally, a detailed developmental history and understanding of family's pattern of interaction is required. Afterwards, the interview may be conducted jointly with parents or caregivers. However, it should be remembered here that individuals from different professional groups emphasize different aspects related to elicitation of CSA.

## ASSOCIATED PSYCHOLOGICAL AIDS

Numerous aids have been utilized for the purpose of elicitation of events and facts related to CSA. However, not every test is useful and the clinician should not take these as a substitute for elicitation of a comprehensive history. Some important ones are as follows:

- (a) Drawings—these have been found useful for assessing and accessing traumatic memories.<sup>104,105</sup> Their utility less in the elicitation of information and emotional aspects that may be suggestive of CSA.
- (b) Anatomical dolls—these are useful for elicitation of a young child's terminology for anatomical parts, and for demonstration by the child. However, these are poor substitutes for history elicitation.
- (c) Psychological testing—certain tests, that is, Rorschach, Personality assessment have been found useful.<sup>106</sup>
- (d) Behavior checklists<sup>107,108</sup> are also available.

## MENTAL STATUS EXAMINATION

Mental status examination is an integral part of evaluation for CSA. This should be carried out as per the developmental level/maturity of the affected person. A detailed observation of the behavior(s) and elicitation of thought process is required. It should be conducted in a relaxed manner, at a neutral location with the help of an audio or videotape. Establishing a good relationship with the child is an integral component, in fact the key to success in terms of elicitation about CSA. However, a certain degree of caution needs to be exercised in that (a) the number of interviews should be kept to the minimum (as multiple interviews may encourage the child to provide incorrect information) and (b) the therapist should not educate or provide new terms or leading statements to the patient. An additional and helpful mode of examination is Play Observation; to be conducted for preadolescents and is a semi-structured examination modality utilizing psychological inputs.

## PHYSICAL EXAMINATION

The physical examination is to be conducted by a mental health professional and pediatrician. This aspect of assessment is valid for children with suspected sexual abuse, and not for adults

with past history of CSA. Traditionally, the examination must be carried out within 72 hours of the molestation, as sperm could be recovered from the adult female genital tract up to 72 hours following penile vaginal intercourse. However, recent recommendations are to bring it down to 24 hours, based on the low yield of forensic evidence from the child's body more than 24 hours after the last sexual contact.<sup>109</sup>

The goals of the examination are identification of injuries that require treatment, to screen and to diagnose STIs, to evaluate (and if possible) so as to reduce the risk of pregnancy, and to document findings of potential forensic value.<sup>24</sup> Three major, specialized forensic techniques that are in vogue are:

- (a) Colposcopy—It is a helpful adjunct. Currently, it is not viewed as an obligatory procedure as most forensically important examination findings are apparent using unaided inspection.<sup>24</sup>
- (b) Foley catheter technique—It is used for hymenal examination. This is a painless procedure. It facilitates the identification of forensically significant physical findings.<sup>24,110</sup>
- (c) Wood's lamp illumination—This test helps to differentiate semen from urine. However, this is to be used to identify suspicious areas or specimens for more definitive forensic testing.<sup>24</sup>
- (d) Confirmatory tests—More intricate tests may be performed for confirming diagnoses of STIs, for example, Gonococcal and Chlamydia cultures, nucleic acid amplification test, enzyme-linked immunosorbent assay, and Western blot for HIV, etc.

A detailed, unaided genital examination is of extreme importance and requires the clinician to be well-versed with anatomical variations of the body, blind to the probable diagnosis of CSA, and experienced in evaluating such cases. This is so as potential bias tends to creep in during examination, if the evaluator has knowledge of history suggestive of CSA.<sup>111</sup> It has been suggested that the prone knee-chest position was the most successful method for detecting hymen lacerations in both pre-pubertal and pubertal girls.<sup>112</sup>

The whole purpose of such a detailed, lengthy and cautious assessment is to ascertain whether or not sexual abuse occurred. Even if CSA is established, certain forensic issues need to be kept in mind and the clinician should ward off these potential confounders, that is, the child making false accusations related to sexual abuse, issues related to whether the child should testify or not? (and what is its credibility and competency), recommendations regarding placement and treatment of children with sexual abuse, and a proper and detailed documentation of the medical report. These issues come into play when there is a high degree of suspicion of sexual abuse, or it is confirmed.

## Treatment

Treatment for CSA is a complicated process. Initially, only adult survivors of CSA received recognition and attention. It is only in the last 15–20 years that specific therapeutic work has been undertaken for managing CSA in childhood. This section focuses in detail on the treatment of sexual abuse during childhood.

**Treatment in primary care:** Firstly and foremostly, it is important to have a welcoming and non-biased attitude toward the child. Hence, rapport establishment is critical at the earliest juncture. Consideration to be given to whether the CSA is acute or chronic, as in acute cases (less than 72 hours after the event), legal processes must have been initiated and completed before proceeding ahead with treatment. Assessments of risks related to physical complications (especially STDs) are mandatory and need to be implemented up to 72 hours of the event.<sup>113</sup>

**Psychological treatment** is complex. Numerous issues need to be kept in mind while dealing with such children.<sup>114</sup> Treatment will be required not only for the affected child, but also for the parents or other family members (who shall be affected by this event). The focus of treatment has to be not only on issues directly related to the abuse, but also to the dysfunctional and problematic relationships associated with it. Numerous practical constraints come into play during the course of treatment viz. the component of confidentiality, secrecy (as desired by the family members), denial on the part of family members (in an effort to ensure secrecy), the legal aspects related to sexual abuse, and liaison with various agencies that are working with the family. However, intervention is helpful because it helps to achieve the break of the abuse and the abusive relationship, and addresses and minimizes the adverse consequences of the abuse.

Different types of psychological interventions have been carried out with some degree of success, including cognitive behavioral therapy (CBT)<sup>115</sup>; dialectic behavior therapy<sup>116</sup>; systems theory based group therapy<sup>117</sup>; and family interventions.<sup>118</sup> For maltreated children, foster care placement can lead to benefits compared with young people who remain at home or those who reunify from foster care, but proper foster care facilities may not be available in many developing nations.

Given the difficulties in treatment, prevention is obviously a high priority. It consists of two approaches—programs catering to high-risk populations and universal education programs.<sup>39</sup> The peri-natal and early childhood programs include the nurse/social worker home visit program where high-risk families are identified and regular visits are made for at least two years. Several trials have demonstrated the efficacy of nurse home visiting<sup>119,120</sup> and Early Start program<sup>121</sup> in reducing abuse in children. Most sexual abuse education programs are aimed at teaching children to avoid sexual victimization or abduction. The efficacy of educational programs in preventing sexual abuse is unclear but it may improve reporting rates.<sup>122</sup>

There is also an issue of future CSA and the prediction of its likelihood as well as prevention. Research has shown that two out three individuals who are sexually victimized will be re-victimized.<sup>123</sup> People, who are re-victimized, show difficulties in interpersonal relationships, coping, affect regulation, and exhibit greater self-blame and shame. Attempts have been made to study cases of CSA for sexual re-victimization in adulthood. It appears that these children exhibit a form of psychological vulnerability determined by factors outside of victim such as family environment or contextual, societal cultural factors including the behavior of

the perpetrator<sup>124</sup> which should be studied. There is need for incorporating risk factors based on evidence to propose future prevention and improve child protection services.<sup>125</sup>

**Drug therapy** is warranted for diagnosable psychiatric morbidity, for example, treating depression. Various forms of non-pharmacological therapies have been tried. The basic aim of these psychological therapies is to provide an opportunity to the child to talk about the abuse and the associated feelings, and gain relief from their inevitable confusion. Furthermore, there is always the need for therapeutic work addressing educational/informative and preventive aspects.

However the degree of psychological disturbance requiring therapy varies from child to child. Hence, the type of treatment and the treatment approach should be individualized.

From India, there is extremely limited literature on treatment that is available. Jain et al.<sup>126</sup> had reported on a case series of five patients with psychiatric illnesses and childhood history of sexual abuse. They reported that psychotherapy (psychological mode of dealing with psychiatric problems) was effective. However there is no literature available to highlight whether any effective treatment (or preventive) strategies for CSA have been developed or implemented.

In relation to treatment and outcome of children with CSA, research tentatively states that some abused children, despite treatment, do not improve or even worsen; the optimal duration of treatment is unclear; dropout rates are very high; it is unlikely that one kind of treatment will suit all children; and boys are harder to treat.

Overall, it can be said that the treatment guidelines and results for CSA are not satisfactory and require a lot of research and clinical input.

## Conclusion

CSA is a common socio-psychological problem that often remains undetected, undiagnosed and untreated. It is associated with a high degree of adverse physical and psychological consequences; some of which can be life threatening. CSA occurs in the background of complex interplay of individual, family-related, and social factors. Assessment for CSA is a tedious and painstaking task associated with a lot of intricacies. In fact, the associated medico-legal and social ramifications complicate the process of evaluation and treatment of CSA. Unsatisfactory assessment and treatment guidelines further compound the difficulties encountered in the process of handling of CSA. The treatment modalities need to be more specific and should be based on explicit conceptual models of psychopathology of CSA and should be based on sound research. Despite the lack of satisfactory treatment for CSA, there is no need to be overly pessimistic in one's approach. It is important to recognize that CSA requires inputs from the psychiatrist at any stage of detection (whether in childhood or in adulthood) so as to alleviate the suffering and manage the adverse psychological consequences arising out of it. Individualized treatment and establishment of a sound therapist-patient relationship still remains the key to success of

treatment of CSA. However, despite a plethora of research from the West, India lags behind in documenting and reporting as well as in intervention studies. Professionals from the medical, social, psychological and legal field should approach, understood and deal with this sensitive issue in an integrated and holistic manner. Nevertheless, sexual abuse in children (i.e., CSA) remains an area where questions definitely outnumber the answers.

Sexual function is a key indicator of quality of life for many of our male patients. Any clinician who has looked after patients with this group of problems will confirm that many men will suffer anxiety and self-worthlessness when they have sexual dysfunction. This feeling of worthlessness will be shared equally by their sexual partners who may rightly or wrongly blame themselves for their partner's problems.

Sexual intercourse is the most essential and pleasurable behavior and satisfactory sex act constitutes an innate and most important desire of a human being. In simple terms, sexual intercourse depends upon a man being able to feel the sexual desire/drive/appetite, develop and retain an erection long enough to enter into vagina and ejaculate, that is, there should be presence and adequacy of excitement, followed by plateau and orgasmic phase. The problems can arise in any one of the phases of sexual act that includes desire/arousability, excitement, and orgasm. Sexual dysfunction may be considered as a relative term because there may be a vast difference between the expectation and performance. Satisfaction/dissatisfaction with sexual relationship is very subjective and individual in nature. More confusion in terminology and understanding of the problem without a detailed history is likely because many common sexual difficulties such as inability to be completely involved in the sex act, inability to relax, situational factors causing reduced interest in sex, too little foreplay etc. can be interpreted as sexual dysfunction.

**Penile erectile function** is a complex process requiring the combined neurological, endocrinological, psychological, and vascular systems. The etiologies of erectile dysfunction (ED) are therefore, frequently overlapping and multifocal. In order to understand the causes and treatment for ED, it is important to understand the anatomy and physiology relating to erections.

The penis is the male organ that contains the urethra which is the channel through which urine and semen leave the body. The penis consists of a base (closest to the body), the shaft and the glans (that part of the penis farthest from the body). It is attached at the base to the bony pelvis. The shaft or main body of the penis consists of three columns of erectile tissue. It has two side parts, the corpora cavernosa and a central part, the

corpus spongiosum. The central part is close to the surface and surrounds the urethra. The corpora cavernosa are cylinders of spongy tissue each surrounded by fibrous tissue (tunica albuginea). The corpora cavernosa are honeycomb like structures that contain muscle and fill with blood following sexual stimulation. It is this engorgement of the erectile tissue that produces a penile erection. The glans is the acorn shaped region at the top of the penis. It is an extension of the corpus spongiosum. In an uncircumcised man the foreskin covers it.

When the penis is flaccid it is under the control of the sympathetic nervous system which is responsible for reflex or unconscious actions. The blood vessels are narrow and the blood flow is low keeping the penis small. When sexual stimulation occurs the parasympathetic nervous system becomes dominant and this leads to vasodilatation and hence filling of the cavernosal tissue with blood. The increased blood in the penis compresses the veins against the fibrous tissue around the corpora. Because of this pressure less blood leaves the penis and an erection occurs. After ejaculation the penis becomes limp, this is a process called detumescence.<sup>1</sup> The sympathetic nervous system is also essential for ejaculation closing the bladder neck. Damage to these nerve pathways can affect the erectile as well as the ejaculatory mechanism.

### What Causes Erectile Dysfunction?

Erectile dysfunction defines the inability to achieve and maintain an erection adequate for satisfactory sexual performance.<sup>2</sup> Epidemiological studies suggest that 5% of men over age 40, 10% of men in their 60s, and 20% of men in their 70s will have ED.<sup>3</sup> Patients over the age of 80 have a 30–50% prevalence of ED.<sup>4</sup> The cause of male erectile dysfunction can be divided into psychological and physical factors. The former include relationship issues, ignorance, fear of failure, and sexual abuse in childhood or adulthood. The physical factors include conditions which affect either blood vessels and/or nerves, for example, hypertension, diabetes, multiple sclerosis, or pelvic surgery. However, it is good to remember that most men will have elements of both psychological and physical factors involved.

## History and Physical Examination

Sexual and general histories are critical ingredients for diagnosis of ED and for planning therapeutic interventions. The history should include history of concomitant diseases, surgical procedures, smoking, current medications, recreational medication, and alcohol use. The sexual history should differentiate primary ED, in which the patient has had no previous erections, and secondary ED, where function has been lost after previous normal sexual function. Associated ejaculatory problems, diminished libido, and changes in the orgasmic experience also need to be investigated and managed; of crucial importance is the timing of onset, as sudden onset is more commonly associated with psychogenic and post-surgical etiologies, whereas gradual onset is more commonly associated with metabolic diseases, such as diabetes and thyroid disorders. It is important to enquire about the presence of erectile function with other partners, during masturbation, as well as for morning and nocturnal erections. The last successful intercourse should be queried, as well as interpersonal issues, relationship with the partner, lifestyle changes, stress, and possible depression should be assessed. Many men present suggesting that their sexual dysfunction is affecting their relationship. While this may be true in some but in many more cases it will be the breakdown of the relationship which is affecting the sexual function.

ED may be associated with medication use, both prescribed and recreational. The general medical part of the examination needs to elicit history suggestive of co-morbid diseases; these include arterial disease (both central and peripheral), diabetes, renal failure, hypercholesterolemia, and neurological abnormalities, including multiple sclerosis and thyroid disease. A surgical history may reveal surgical procedures associated with ED, including radical pelvic surgery such as abdominal perineal resection, prostatectomy, cystectomy, and pelvic trauma.

Physical examination is focused on the genitourinary system. The penis must be carefully examined to identify abnormalities, such as micropenis, Peyronie disease, or hypospadias. Testicular examination may reveal small, soft, atrophic testes, or absent testes. One of the major reasons for the examination is to be able to reassure the patient as a significant number of men will admit that one of their concerns is about the adequacy of the size of the penis.

## Laboratory Studies

Laboratory studies help identify the co-morbidities associated with ED. Initially these need to include fasting blood sugar levels, a lipid profile and early morning testosterone estimation. Testosterone must be evaluated in the morning, since the diurnal variation in physiological excretion results in the highest values between 0800 and 1000 hours; a late-afternoon testosterone may be low or borderline because of this diurnal variation. Primary or hypergonadotrophic hypogonadism is associated with an elevation in the pituitary hormones, LH, and follicle-stimulating hormone. Most patients, however, have isolated decreases in serum testosterone associated with testicular production deficiencies.<sup>2</sup>

The primary goal of management of ED is to enable the individual or couple to enjoy a satisfactory sexual experience. This involves:

- Identifying and treating any treatable causes of ED.
- Initiating lifestyle change and risk factor modification.
- Providing education and counseling to patients and their partners.

## First-line Therapy

Psychosexual therapy either alone or alongside the couple's relationship therapy is indicated particularly where the patient and/or partner identify significant psychological contribution to the problem or as perpetuating the problem. It is also important to remember that the initial problem may not be with the man but with his partner.

As sex is a subjective experience, it is inevitable that all couples affected by sexual dysfunction have at least some psychological component to their problem. Almost all couples will benefit from simple sex education, and clinicians treating ED should be able to provide this. Helping men to achieve an understanding of their physiological sexual response, the effects of ageing, concurrent disease, and medication may also be important. An improved understanding of the similarities and differences in sexual interest and response in men and women may be beneficial. The clinician should be able to provide simple behavioral advice regarding foreplay, sexual activity, and on the integration of medication into the couple's sexual behavior.

Formal cognitive-behavioral interventions should be provided by appropriately trained and experienced therapists. They may be of some benefit in all men but are probably best used in men with a predominantly psychogenic component in ED. Such interventions are less likely to be beneficial in men with complete ED of predominantly organic etiology. Concurrent use of medication, such as phosphodiesterase type 5 (PDE5) inhibitors, is not precluded in men engaged in cognitive-behavioral therapy, and a combined pharmacotherapeutic-psychotherapeutic approach may be more effective than using these interventions individually or consecutively.<sup>5</sup>

Drugs that inhibit PDE5 increase arterial blood flow, which leads to smooth muscle relaxation, vasodilation, and penile erection.<sup>6</sup> Three potent selective PDE5 inhibitors have been approved: sildenafil, tadalafil, and vardenafil. These medications have proven efficacy and safety both in non-selected populations of men with ED and in specific sub-groups of patients (e.g., men with diabetes and those who have had a prostatectomy).<sup>7-9</sup> The major difference in these drugs is that sildenafil and vardenafil are relatively short-acting drugs, having a half life of approximately 4 hours, whereas tadalafil has a significantly longer half life of 17.5 hours. PDE5 inhibitors are not initiators of erection but require sexual stimulation in order to facilitate an erection.<sup>7-9</sup> It is currently recommended that patients should receive a minimum of eight doses of the highest tolerated dose of a PDE5 inhibitor (taken sequentially) with failure of sexual stimulation at maximum dose before classifying a patient as a non-responder.

Approximately 25% of patients do not respond to PDE5 inhibitors. So-called failure may be due to suboptimal counseling at the initial consultation, which should aim to ensure that the patient understands how to take the tablets properly and to return to the doctor if they are dissatisfied. Cost of drug therapy and reluctance of the partner are frequent reasons for unsatisfactory response.<sup>10</sup> Several measures are described in the literature to salvage patients, clearly identified as non-responders:

- Re-counseling on proper use
- Optimal treatment of concurrent diseases and frequent re-evaluation for new risk factors.
- Treatment of concurrent hypogonadism. It is well-established that testosterone regulates the expression of PDE5 and the responsiveness of PDE5 inhibitors in the corpus cavernosum<sup>11,12</sup> and several studies have shown that patients can be salvaged by treating low or low-normal levels of testosterone.<sup>13,14</sup>
- Occasionally, patients may respond to one drug when another has failed.<sup>15</sup>
- More frequent dosing regimens,<sup>15,16</sup> for example, Cialis.

## SAFETY OF PDE5 INHIBITORS AND DRUG INTERACTIONS

There is no evidence that PDE5 inhibitors significantly increase the rate of myocardial infarction. PDE5 inhibitors do not adversely affect total exercise time or time to ischemia during exercise testing in men with stable angina. In fact, all three PDE5 inhibitors may improve the time to ST elevation.<sup>17</sup>

Organic nitrates (e.g., nitroglycerine, isosorbide mononitrate, isosorbide dinitrate), other nitrate preparations used to treat angina such as nicorandil and recreational drugs such as amyl nitrate (poppers) are absolute contraindications with PDE5 inhibitors. Combined use could result in unpredictable falls in blood pressure and, potentially, catastrophic hypotension. Nitrates are usually prescribed for the treatment of angina; unlike calcium channel blockers and beta-blockers, they convey no prognostic benefit with regard to the prevention of further coronary episodes.<sup>18</sup> As such, it is often appropriate for the physician to review their use in an affected individual and consider their replacement with other anti-anginal agents.<sup>19</sup> Co-administration of PDE5 inhibitors with antihypertensive agents may result in a small additive drop in the blood pressure, which does not usually cause significant orthostatic hypotension. Generally, the adverse event profile of PDE5 inhibitors is not worsened by the concomitant use of antihypertensive medicines.

Alpha-blockers have some interaction with PDE5 inhibitors. Under some conditions, this interaction may result in orthostatic hypotension, and PDE5 inhibitors should be used with caution in patients receiving alpha-blockers. These interactions are more pronounced when PDE5 inhibitors are given to healthy volunteers not previously taking alpha blockers and are rarely of clinical significance when the drugs are not started simultaneously. The Summary of Product Characteristics for alpha-blocking drugs do not carry warnings for use with PDE5 inhibitors.

## Second-line Therapy

### VACUUM ERECTION DEVICES

The principle of vacuum erection devices is simple. A cylinder is placed over the penis, air is pumped out with an attached pump and the resulting tumescence is maintained by a constriction ring around the base of the penis.

- Vacuum devices are highly effective in inducing erections regardless of the etiology of the ED.<sup>20</sup>
- Reported satisfaction rates vary considerably from 35 to 84%.<sup>20</sup>
- Long-term usage of vacuum devices also varies but is considerably higher than for self-injection therapy.
- Most men who are satisfied with vacuum devices continue to use them long-term.
- Adverse effects include bruising, local pain, and failure to ejaculate can occur. Partners sometimes report that the penis feels cold.
- Serious adverse events are very rare but skin necrosis has been reported.

Vacuum devices are contraindicated in men with bleeding disorders or in those taking anticoagulant therapy. They work best if the man and his partner have a positive attitude to them and sufficient time has been spent demonstrating their use.

### INTRACAVERNOUS INJECTION THERAPY

It is the most effective form of pharmacotherapy for ED and has been used for more than 20 years.<sup>18</sup> Providing the blood supply is good, and an excellent result can be achieved in most men. It does not require an intact nerve supply and can therefore be highly effective after spinal cord injuries and after major pelvic surgery such as after radical prostatectomy. However, because of the invasive nature of the procedure it is not acceptable to some patients and their partners, and this may result in poor long-term compliance in those who do try it. Compliance may be a particular problem if the procedure is not explained clearly and fully at first consultation and if adequate support and follow-up visits are not provided.

Alprostadil was the first licensed drug approved for intracavernous ED treatment. Alprostadil can be used in doses from 5–40 µg. The erection occurs typically 5–15 minutes after penile injection and frequently lasts 30–40 minutes, although the duration can be dose dependent. In patients with limited manual dexterity and in some other groups, the partner may be taught the technique. Partner participation in the consultation and training program can be valuable and improve long-term compliance. Some patients prefer to use an automatic injection pen that avoids a view of the needle and can help with the fear of penile puncture.

Efficacy and safety of alprostadil is summarized below:

- Efficacy rates are high—around 70–80% in the general ED population and higher in those without vascular disease

- Once properly taught the procedure has a high reproducibility and high satisfaction rate for both patients and their partners
- Long-term compliance rates however, can be low with as many as 50% of patients stopping in the first 2–3 months
- Careful counseling in the early stages with an assured availability of advice in the first few weeks can improve compliance
- Adverse effects of intracavernous alprostadil include post-injection penile pain (in up to half of the patients after at least some of their injections)
- Other complications include priapism (1%) and fibrosis (2%)
- Contraindications are few but include a history of hypersensitivity to alprostadil, a risk of priapism and bleeding disorders.

MUSE is an acronym for Medicated Urethral System for Erection. Patients are told to void to make sure the urethra is moist, the pellet is inserted into the urethra via a small applicator and the penis massaged. Alprostadil is delivered into the penile urethra and is absorbed through the epithelium into the venous channels of the corpus spongiosum. It reaches the vascular smooth muscle of the corpora cavernosum by retrograde flow through emissary veins, encouraged by penile massage at the time of administration. Use of MUSE results in erections in approximately 30–60% of patients.<sup>18</sup>

- In clinical practice only the higher dosages of 500 µg and 1000 µg are effective
- Application of a constriction ring at the base of the penis may help in some patients,
- Side effects include penile pain (30–40%) and dizziness (2–10%)
- Penile fibrosis and priapism can rarely (<1%) occur
- Urethral bleeding and urinary infection may result from faulty technique

This is a less invasive but also less effective treatment than intracavernosal injection therapy.

### Third-line Therapy

Penile prostheses should be offered to all patients who are either unwilling to consider, or fail to respond to, are unable to continue with medical therapy or external devices. All patients and their partners should be counseled pre-operatively, see and handle all the available devices and if possible speak to other patients who have had surgery.

Penile prostheses are particularly suitable for those with severe organic ED, especially if the cause is Peyronie disease or post priapism. All patients should be given a choice of either a malleable or inflatable prosthesis. Satisfaction rates of 89% were shown in one series of 434 implants. High rates are mainly due to the improved mechanical reliability of the new devices. Five-year survival of these devices is 93% but a revision rate of 7% per year can be expected.<sup>21</sup>

The advantages of penile prosthesis include:

- Long-term efficacy with a high satisfaction rate
- No need for medication
- Improved ability to lead a normal sexual life.

However, patients must be medically fit for surgery and accept potential complications of infection, erosion and mechanical failure which may need re-operation. The initial cost is high but manufacturers do offer a lifetime guarantee.

### Ejaculatory Dysfunction

Ejaculatory dysfunction comprises premature ejaculation, delayed ejaculation, anejaculation, low ejaculate volume, retrograde ejaculation, and painful ejaculation.

All patients should be asked about whether the problem has been lifelong or recently acquired. History taking should include a full history of previous illness, including that of psychotic or depressive illness, any injuries or operations, particularly pertaining to neck, spinal or pelvic injuries, or operations, and any urinary tract operation performed during infancy. Any urinary symptoms should be noted, including assessment of whether the urine flow is good and whether the urine stream sprays (spraying indicates disturbance of normal urethral anatomy). All prescribed medicines and any other medicines or alternative treatments should be noted. It is also important to enquire about alcohol and recreational drug use.

#### PREMATURE EJACULATION

Premature ejaculation (PE) is the commonest male sexual dysfunction and affects approximately 20–30% of the population. Premature ejaculation is the inability to control ejaculation for a “sufficient” length of time during vaginal penetration, which causes distress to the patient and/or his partner. There is no definition of “sufficiency.” For the purposes of scientific studies, a practical definition is an intravaginal latency time of less than 60 seconds. This can be assessed with a stopwatch. More recent literature suggests that more “patient-related outcomes” such as a feeling of control could be a better measure.

Premature ejaculation may be physiological or psychological; it would be primary, lifelong problem or secondary due to physical disorders such as thyroid over-activity, neural or pelvic pathology.

Treatments for premature ejaculation include:

- Simple reassurance
- Ease and squeeze technique
- Topical local anesthetic cream or spray applied 15–20 minutes (but not longer) before sexual contact
- Treatment with selective serotonin uptake inhibitors (SSRIs) (On demand)
- Treatment with SSRIs or tricyclics (Daily)
- PDE5 inhibitors
- Combination topical anesthetic and SSRI

For lifelong PE, the choice lies between topical anesthetics or drugs because reassurance and ease and squeeze are ineffective. At present, the treatment with drugs involves mainly use of SSRIs and the tricyclic antidepressant clomipramine. The main options are paroxetine 20–40 mg, sertraline 50–100 mg, and fluoxetine 20–40 mg. However, side effects of drug treatment can be bothersome: sleepiness at the time of coitus with SSRIs and next day nausea can occur with clomipramine. Drug treatment is evolving, and it has been proposed that the most efficacious drug is likely to be a combination of a 5-hydroxytryptamine (5-HT)<sub>2c</sub> receptor stimulation and a 5-HT<sub>1A</sub> receptor inhibitor. A meta-analysis of the studies of all drug treatments highlighted the limitations of many of the studies on which treatment is now based.<sup>22</sup>

### DELAYED EJACULATION/ANEJACULATION

Ejaculation is considered to be delayed when excessive stimulation is required to obtain orgasm with ejaculation. This is a subjective diagnosis and it is difficult to distinguish when delay becomes pathological. Overall, if the patient complains of delayed ejaculation his complaint should be taken at face value. Anejaculation is the complete absence of antegrade or retrograde ejaculation but with preservation of the sensation of orgasm.

The underlying etiology may be psychogenic, neurogenic, drug-related, or obstructive. Neurogenic anejaculation is seen in spinal cord injury, cauda equina lesions, following retroperitoneal surgery (e.g., lymphadenectomy, aortic aneurysm, horseshoe kidney), following colorectal surgery, in association with Parkinson disease, multiple sclerosis, and diabetic autonomic neuropathy. Drug-related anejaculation may occur with antihypertensives, antipsychotics, antidepressants, and alcohol. Obstructive anejaculation may occur with congenital or acquired blockage of the ejaculatory ducts. There may be failure of development of the prostate or seminal vesicles or following prolonged inflammation of the prostate with fibrosis or when the prostate is replaced by tumor. The condition may occur for social or religious reasons. Some young men learn to masturbate without ejaculation. The consequence of these practices is deconditioning of the ejaculatory reflex, and ultimately this may cause anejaculation. It can also sometimes cause orgasmic pain, hematospermia, and congestive prostatitis.

Often it is not possible to correct any underlying abnormality, for example, after retroperitoneal lymph node dissection, and in such cases treatment results are poor. Provided the lumbosacral segments of the spinal cord are intact, some men are helped by the use of a vibrator applied at the frenulum using 100 Hz and 6000 vibrations per minute. Electroejaculation can be used to obtain sperm and is successful in 90% of men. Prostatic massage has been used to obtain sperm from men with psychogenic anejaculation, and when possible this is logistically easier than electroejaculation, which requires general anesthesia. With lack of ejaculation, an underlying abnormality such as urethral stricture should be corrected. Sympathomimetic drugs such as yohimbine have also been successfully used.

### LACK OF FORCE OF EJACULATION/ LOW EJACULATE VOLUME

Sometimes patients complain of lack of force or low ejaculatory volume. This is a subjective complaint. In overt cases, there is a history of failure of any spurt of ejaculation at the time of orgasm but instead seepage of semen for several minutes after orgasm. The complaint of low ejaculate volume is self-explanatory, although most men have no idea of what normal ejaculation volume should be but nevertheless can distinguish that their ejaculate volume has diminished.

With ageing, there is a reduction in muscle tone of the urethral wall and one of the manifestations of this is reduced propulsion of ejaculation. It also occurs when there has been disruption of the normal urethral musculature, for example, with urethral pathology such as stricture and diverticulum and following substitution urethroplasty. Reduced ejaculate volume may occur because of androgen deficiency. The secretions of the prostate and seminal vesicles are androgen-dependent and ejaculate volume is a good indicator of androgen sufficiency. Also, ejaculate volume may be reduced if there is severe end-stage inflammation of the prostate and seminal vesicles.

### PAINFUL EJACULATION

This is a painful sensation felt in the perineum, urethra or urethral meatus during and sometimes after ejaculation. It most commonly occurs with prostatitis and urethritis and often there is associated painful urination. The condition may or may not be distinguishable from orgasmic pain, which is usually neurogenic in etiology and poorly localized.

### RETROGRADE EJACULATION

Retrograde ejaculation can be caused by any condition that causes failure of bladder neck closure or an increased resistance at the apex of the prostate so that the least line of resistance to passage of semen is back into the bladder. Neurogenic retrograde ejaculation occurs with neurological conditions that cause failure of bladder neck closure or spasticity of the pelvic floor or both. Conditions that can cause this include spinal cord injury, cauda equina lesions, spinal dysraphism, and tethered spinal cord. It may follow disruption of the sympathetic chain by retroperitoneal surgery, for example, following lymphadenectomy, sympathectomy, and aortic aneurysm surgery. It may follow disruption of the pelvic plexus by pelvic surgery, including colorectal and anal surgery. It may occur with generalized neurological diseases such as multiple sclerosis and diabetic autonomic neuropathy (juvenile diabetes).

Various drugs interfere with bladder neck function. These include antihypertensives, alpha-1 adrenoreceptor antagonists, antipsychotics with an alpha-blocking effect, for example, thioridazine and risperidone, and antidepressants.

Anatomical bladder neck incompetence can occur in association with congenital defects of the trigone, including hemitrigone and with ectopic ureters following bladder neck surgery, bladder neck resection, and prostatectomy.

Obstruction at the prostate can be caused by congenital abnormalities such as ectopic ureterocele, urogenital sinus remnants, membranous urethral stricture and verumontanum hyperplasia.

Retrograde ejaculation can be distinguished from anejaculation by the finding of sperm in the postorgasmic urine.

Treatments to restore antegrade ejaculation include the use of alpha receptor stimulating drugs such as ephedrine and amezinium (an antihypotensive agent) or restoration of bladder neck competence by injection of bulking agents or bladder neck surgery. However, the chance of success following the injection of bulking agents or surgical treatment has to be balanced against the risk of causing urinary tract obstruction. Treatments to enable fertility include sperm recovery from the urine, bladder washings and microsurgical retrieval of epididymal sperm and intra-cytoplasm sperm injection.

## Orgasm Dysfunction

Men present less infrequently with disorders of orgasm compared with women. The history given is of a lack of external ejaculation. It should be determined whether there is a lack of orgasm, in which case the problem is one of anorgasmia, or whether orgasm is present but there is a lack of external ejaculation. The patient should be asked about nocturnal emissions. If these occur and if there is no other disease process, then the problem is more likely to be one of psychogenic anejaculation. Retrograde ejaculation is the more likely diagnosis if there is a history of passage of cloudy material in the postorgasmic urine.

Anorgasmia is the inability to reach orgasm; if the spinal cord is intact it is usually associated with anejaculation. After spinal injury and with spinal cord transection, it may be possible to stimulate reflex ejaculation, but there is no sensation of orgasm. Altered sensation and reduced intensity of orgasm often follows radical prostatic surgery. There are two components to this: in part the altered sensation is because of the altered anatomy and the lack of the feeling of the ejaculate passing through the prostate and urethra, but also there is reduced intensity of sensation because of damage to local neural pathways, for example, as a result of spinal cord pathology, following fracture of the posterior pelvis with damage to the pelvis plexus, and after radical pelvic surgery, or radical prostate surgery.

In all cases of ejaculatory problem, the first approach is to treat any underlying disease process, for example, ensure good diabetic control in a man with diabetes, treat prostatitis, etc. Any medication that may be causing the problem should be stopped, if possible, or substituted. Also, treatment depends on the type of ejaculation disorder and whether the man is seeking to enable his fertility, normalize his sexual function or both. In terms of fertility, it is often appropriate at an early stage in treatment to discuss with the patient and his partner home insemination techniques and sperm retrieval techniques, such as microepididymal sperm aspiration, because the treatment of

the underlying ejaculatory disorder may not be successful or may take a long time. In addition, treatment depends on the nature of the ejaculatory problem.

“Libido” is a Latin word meaning “desire, pleasure.” Complaints of “lack or loss of sexual desire” are much more common than those of hypersexuality among men. Many patients presenting with the complaints of reduced sexual desire will actually have other sexual dysfunctions that account for their loss of interest in sex, for example, ED or PE because sexual experience for them is not reinforcing. Equally, the sexual dysfunction may actually lie with their partner, for example, a man loses interest in sex if his partner has anorgasmia or dyspareunia.

Subjects with hypoactive sexual desire are deficient in sexual fantasies and desire for sexual activities. This condition is different from sexual aversion where sexual activity is avoided due to anxiety. Loss of libido or sexual desire can be a lifelong pattern or may occur after a period of good sexual interest or may be only contextual, that is, with a certain partner. Assessment of individuals with hypoactive sexual desire requires full evaluation of medical causes, psychological factors, and relationship issues. There are several conditions or co-morbidities which must be excluded in men who present with decreased libido. These include

- Primary and secondary hypogonadism
- Hypothyroidism
- Pituitary adenomas.
- Mental health problems such as depression, schizophrenia, and substance abuse.

There are also certain commonly prescribed drugs which can lead to decreased desire, which include

- Antidepressants
- Antihypertensives
- Phenothiazines
- Diuretics
- Hypnotics

## Treatment

This is the most difficult of all the sexual dysfunctions to treat. Testosterone has been tried in men and women with inconsistent results. Moreover, masculinizing side effects of testosterone pose a serious issue in females. In a recent study<sup>28</sup> bupropion sustained release has been tried in non-depressed females with low sexual desire—29% of the patients responded to this treatment. Basic treatment involves a combination of psychotherapeutic techniques. Cognitive therapy can be used to change the maladaptive ways of thinking: like the partners may or may not want sex at the same time; or behavior therapy to increase the pleasure out of sexual activity making it a rewarding and pleasurable experience; or marital therapy to improve the relationship between partners. In case of any underlying primary pathology in medical or psychiatric domain, the respective conditions should be appropriately treated. If hypoactive sexual desire occurs secondary to prescription

medicine, then intervention in the form of dose reduction or drug holiday or change of drug or change of treatment strategy to non-drug methods is warranted. However, there are no pharmacological antidotes nor is there any libido pill.

### Summary

Sexual dysfunction involves contribution of biological, psychological, and social factors. Several medical causes such as heart disease, cancer, renal failure, diabetes, neurological disorders, or many chronic medical illnesses can impair sexual function. There are many medications used for common medical/surgical problems like anticholinergic agents, atorvastatin, calcium channel blockers, antihypertensives, anticonvulsants, psychotropic drugs, hypnotics and sedatives, etc. that produce significant sexual dysfunction. It is important to be aware of the problem and explore into all relevant issues so that the problem can be adequately treated. Sexual dysfunction affects the quality of life of individuals and can contribute to secondary morbidity in the psychological or social domains. Physicians have a major role in preventing as well as treating this condition among their patients.

## Human Sexuality

Generally speaking, human sexuality is how people experience the erotica and express themselves as sexual beings. Biologically, sexuality can include sexual intercourse, sexual contact in all its forms, and medical concerns about the physiological as well as psychological aspects of sexual behavior. Sociologically, it can cover the cultural, political, and legal aspects; and philosophically, it can extend into the moral, ethical, theological, spiritual, or religious aspects.<sup>1</sup> In addition, the biological aspects of human sexuality deal with human reproduction and the physical means with which to carry it out. They also deal with the influence of biological factors on other aspects of sexuality, such as organic and neurological responses<sup>2</sup> heredity, hormonal issues, gender issues, and sexual dysfunction.<sup>1</sup>

The ultimate sexual pleasure is the “orgasm.” However, women find it harder than men to experience orgasm because of the increased level of stimulation needed by them to reach orgasm. Majority of women experience orgasm by intense clitoral stimulation, while the orgasm may be harder to achieve by vaginal stimulation. The most sensitive area in a woman's body is the Grafenberg spot (G-spot) which is found in the vagina. If properly stimulated, the G-spot may cause very strong orgasms, even stronger than the ones reached after clitoral stimulation.<sup>3</sup> A number of women are able to experience multiple orgasms even though these are very rarely experienced. The serial orgasms may occur immediately one after another but separated by few minutes.<sup>4</sup>

Women are able to achieve multiple orgasms due to the fact that they do not experience any kind of refractory period as men do after the first orgasm. Theoretically, if stimulation is not interrupted, most women should be able to achieve multiple orgasms. The variety of erogenous zones that a woman has on her body and that can be stimulated are an advantage that women have and men do not.<sup>5</sup> During sexual intercourse, it is usual that men stop the stimulation process in a woman, and this may be one of the reasons why many women do not actually achieve more than one orgasm.

## Basic Differences between Men and Women's Sexuality

A large body of scientific research documents four important gender differences in sexuality. First, men showed moderately higher levels of sexual desire than women.<sup>6</sup> Second, women gained slightly higher than men on general sexual satisfaction within the relationship. Both men and women are most sexually satisfied within an ongoing relationship;<sup>7</sup> however, women may emphasize relational aspects of sexuality slightly more than men,<sup>8</sup> and therefore may fully appreciate the benefits that come from building a stable sex life within an ongoing relationship with a familiar partner. Third, women tended to have slightly higher than men on average level of sexual satisfaction across a wide range of non-orgasmic sexual practices. Given the gender differences in sexual desire, it is very easy to assume that men will “like sex” more than women. That view is supported by one large-scale national survey, which found that men rated almost every one of a list of sexual practices as more appealing than did women.<sup>7</sup> Finally, women's sexuality tends to be more susceptible and capable of change over time. These male–female differences are pervasive, affecting thoughts and feelings as well as behavior, and they characterize not only heterosexuals but lesbians and gay men as well.<sup>8</sup>

For sexual arousal, men and women are different in terms of sexual arousal patterns. Sexual arousal is category-specific in men; heterosexual men are more aroused by female than by male sexual stimuli, whereas homosexual men show the opposite pattern. There is reason to believe that female sexual arousal is organized differently. In contrast to men, both heterosexual and homosexual women experienced strong genital arousal to both male and female sexual stimuli.<sup>9</sup>

## Model of Human Sexual Response

The pioneering research of the human sexual response, and the diagnosis and treatment of sexual disorders and functions, was carried out by Masters and Johnson in 1966.<sup>10,11</sup> Their laboratory-

based observational studies have led to a primary understanding of the physiology of the human sexual response. Later studies have tended merely to confirm or to modify details of the observations they presented in their book, *Human Sexual Response*, over 40 years ago.

The sexual responses of men and women have many similarities in most respects, and have both subjective and physiological components. Subjectively, sexual arousal is how aroused people believe or say they are, while physiological arousal is measured as the extent of physiological response. Bancroft<sup>12</sup> has proposed that at least four major components of sexual arousal need to be independently addressed: (i) sexual appetite or drive, including determinants of both motivation and arousability; (ii) central arousal, including cognitive or attentional factors that define a given stimulus as sexual; (iii) genital responses; and (iv) peripheral indices of arousal, encompassing nongenital somatic, and autonomic changes. Those are the interaction effects between different levels of psychophysiological response.

In general, a woman's sexual responses are triggered by different stimuli from those of a man, and they are more dependent on closeness and affection. When sexual stimulation is maintained, it can lead to a peak or culmination of the induced sexual arousal that causes certain mental (subjective) and physical manifestations (physiologic) that are normally described as the experience of an orgasm. The woman's sexual response is an extremely individual process, and varies in the physical, mental, and emotional reactions to sexual stimulation. The intensity of orgasm also varies widely between individuals, especially women, some can have orgasms so intense and overpowering that they become momentarily unconscious,<sup>13</sup> yet others may have difficulty in recognizing the changes. A number of women have the biological capacity for multiple orgasms.<sup>10,14</sup>

Several models of human sexual response have been proposed by different groups of workers:

### MASTERS AND JOHNSON FOUR-PHASE MODEL

This model proposes four phases, occurring in the same sequence in both sexes; and these are the excitement (E), plateau (P), orgasmic (O), and resolution (R) phases. All phases vary from person to person and situation to situation.<sup>10</sup> This EPOR model—the so-called linear model—is still the standard version followed today.

**(1) Excitement:** Any form of sexual stimulation, including masturbation, manual stimulation by one's partner, oral sex, and fantasy causes the early basic physiological responses of vasocongestion, myotonia (voluntary flexing, involuntary contraction), increased heart and breathing rate, increased blood pressure, and the sex flush. The duration of this phase can last from less than a minute to over several hours. In women, the clitoral shaft gets bigger, the labia majora separate, and the labia minora enlarge while often becoming darker. Some women produce a considerable amount of lubrication at this point, though others only produce a small amount.

Genital vasocongestion results from both parasympathetic and sympathetic nerves releasing nitric oxide and vasointestinal polypeptide which mediate vasodilatation, and acetylcholine which blocks noradrenergic, vasoconstrictive mechanisms and promotes endothelial release of nitric oxide. The relaxation of vaginal smooth muscle permits vaginal expansion, and arteriolar dilatation increases the transudation of interstitial fluid, which promotes lubrication.<sup>15</sup>

**(2) Plateau:** The sexual tension continues to grow as a precursor to orgasm, without a clearly demarked point from excitement to plateau. Everything that happened in the excitement phase continues and becomes more prominent; continued vasocongestion and coloration, continued myotonia, continued increased heart and breathing rate, continued increase in blood pressure, and continued sex flush. The duration of this phase can be very brief, from 2 seconds to a few minutes. During the plateau phase, the clitoris retracts under its hood, while the outer one-third of the vagina becomes especially engorged with blood, creating a structure called "the orgasmic platform."

**(3) Orgasm:** The orgasm is the shortest phase of the sexual response cycle, typically lasting only several seconds, and women can have a slightly longer orgasm than men. During orgasm, the entrance to the vagina contracts rhythmically and the woman experiences waves of intense pleasure, due to rhythmic contraction of the uterus and the orgasmic platform, while the myotonia also causes facial grimaces and twitches in the hands and feet. However, many women may not reach the orgasm phase in every sexual act.

**(4) Resolution:** In this stage, the body returns to its original, nonexcited state. Some of the changes occur rapidly, whereas others take more time. The resolution phase begins immediately after orgasm if there is no additional stimulation.

The refractory period occurs during the resolution phase, and is the time when a man cannot reach excitement, plateau, or orgasm through any kind of sexual stimulation. This period can last from a few minutes to days, depending on his age and frequency of sexual activity, among other things. Women do not experience a refractory period, and they are capable of reaching orgasm from anywhere during resolution. Women have the potential to have multiple orgasms, but a woman may not want to have a second or third orgasm.

### KAPLAN MODEL

In 1974, Kaplan proposed that before the excitement phase (phase E), there should be a desire phase (phase D), and suggested a three-stage model of sexual response: desire, excitement, and orgasm (DEO).<sup>16</sup> After this, Robinson concluded convincingly that the Plateau phase (P phase) was simply the final end of the E phase.<sup>17</sup> Following this Kaplan proposed that the sexual cycle consists of four successive phases, viz., desire, excitement (arousal), orgasm, and resolution (DEOR model), which later on became an accepted model.<sup>18</sup>

## LEVIN MODEL

In this model, the initiating phase of sexual desire (D) was divided into spontaneous desire (D1) and responsive desire (D2), and proposed as the D1D2EOR model, and the P phase was deemed unnecessary as it was actually a phase of increasing sexual excitement and the end of the E phase.<sup>19</sup> The majority of women's sexual desire is actually responsive rather than spontaneous, for instance, a reaction to a partner's sexual interest rather than a spontaneous stirring of her own libido.<sup>20</sup> Moreover, it has been recognized and well-understood that at least one-third of women never experience spontaneous sexual desire.<sup>21</sup> In addition, women may not even experience all of the phases; for example, there may be orgasm and satisfaction without desire, or desire and arousal without orgasm.<sup>22</sup>

## CIRCULAR MODEL

In 1997, Whipple and Brash–McGeer modified the linear model of the sexual response pattern for women, that is, seduction (encompassing desire), sensations (excitement and plateau), surrender (orgasm), and reflection (resolution).<sup>23</sup> This model demonstrated that pleasant and satisfactory sexual experiences may have a reinforcing effect on a woman, leading to the seduction phase and vice versa, on the other hand Basson's circular model emphasizes subjective and interpersonal aspects of emotional and relational intimacy.<sup>20,24</sup> The latter model differs from linear models, and focuses primarily on physical aspects, and has variously modified and included sequentially circular phases of: (i) sexual stimuli with appropriate context, biological, and/or psychological; (ii) subjective sexual arousal which, when sufficiently intense, leads to sexual satisfaction with/without orgasm; (iii) nonsexual rewards; emotional intimacy, well-being, and lack of negative effects from sexual avoidance; (iv) multiple reasons/incentives for instigating or agreeing to sex; and (v) motivation to a willingness to find/be receptive. The spontaneous or innate desire, as reflected by sexual thinking/fantasizing/wanting of sexual sensation per se, may or may not expand the cycle.<sup>24</sup>

## Prevalence of Sexual Dysfunction

A slice of data from the United States National Health and Social Life Survey 1992, for among 1749 women and 1410 men aged 18–59 years, gave figures of sexual dysfunction; 43% for women, and 31% in men. The 43% figure has been questioned because the subject was included into a sexual dysfunction group if the respondent said only “one yes” of seven questions about sexual problems. Later, in an article in *The Journal of American Medical Association* it was stated that its data were not equivalent to a clinical diagnosis.<sup>25</sup>

The National Survey of Sexual Attitudes and Lifestyles 2000 was conducted in the UK among a population of 11,161 respondents aged 16–44 years.<sup>26,27</sup> The questionnaire was based on those used in US survey, and measured the main dimensions of sexual dysfunction, as defined in the International Classification

of Diseases, 10th revision (ICD-10). Persistent sexual problems, lasting at least 6 months in the previous year, were more prevalent among women (15.6%) than among men (6.2%). The most common problems among women were inability to experience orgasm, and painful intercourse, while the main problems in men included lacking interest in sex, early (premature) orgasm, and anxiety about performance. The most common persistent problem among women was lack of interest in sex, and in men it was of early orgasm. Furthermore, short-term sexual problems were relatively common with over a third of men and half of women experiencing at least one sexual problem of at least 1 month's duration in the previous year.<sup>27</sup>

On account of several reasons, Bancroft suggested that there is need to observe caution about medicalization of these clinical issues on account of several reasons: (i) men-women differ in sexuality—women have less need for their sexuality to be influenced by reproductive hormones, and are more susceptible to the repressive effects of social constraints on sexuality; (ii) there is difficulty in predicting when pharmacological effects on sexual response will be beneficial, due to problems in distinguishing between adaptive inhibitions of the response from those that are maladaptive dysfunctions; and (iii) to define when is a sexual problem a sexual dysfunction? Many cases of impaired sexual response or interest in women are psychologically understandable and hence can be considered as adaptive reactions to problems in the sexual relationship, and therefore not dysfunctions.<sup>28</sup>

## Definition of Sexual Dysfunction

The range of sexual problems can be classified as sexual complaints, sexual dysfunction, or disorders. Disorders encompass dysfunction associated with personal distress. Therefore, abnormal function or sexual dissatisfaction can exist without a disorder being present.<sup>29</sup> Because of the broad spectrum of sexual problems, the indicators of severity should also be described such as (i) duration of the problem, lasting more than 1 month or 6 months in the previous year; and (ii) avoidance of sex. The problems of sexual function are relatively common, but persistent problems are much less so.

Help-seeking behavior for sexual problems reflects on the severity of the issues, whereas, the need for professional intervention depends on the patient's perception and on the underlying causes. With regards to obtaining relief for sexual dysfunction, a study in Britain showed that 74.3% of women consulted their general practitioner, while the corresponding figure for men was 63.8%.<sup>30</sup> 4.8% of women sought help at a genitourinary clinic, whereas for men the figure was 9.2%. However, since the licensing of sildenafil more men present with sexual problems at genitourinary clinics.<sup>31</sup>

Previous definitions of women's sexual dysfunction were based on the linear model of human sexual response of Masters and Johnson, and subsequently revised by Kaplan. Traditionally, sexual dysfunction is defined as a disturbance in, or pain, during, the sexual response. However, this is more difficult to diagnose and treat in women than it is in men because of the complexity of the female sexual response. In 1998, the Sexual Function

Health Council of the American Foundation of Urologic Disease revised pre-existing definitions and classifications of Female Sexual Dysfunction.<sup>32</sup> Medical risk factors, etiologies, and psychological aspects were classified into four categories of: disorders of desire, arousal disorders, orgasmic disorders, and sexual pain disorders:

- Hypoactive sexual disorder is the persistent or recurrent deficiency (or absence) of sexual fantasies/thoughts and/or receptivity to, sexual activity, which causes personal distress. Uncommonly, some women may have sexual aversion disorder which is persistent or recurring phobic aversion to, and avoidance of, sexual contact with a sexual partner, which causes personal distress.
- Sexual arousal disorder is the persistent or recurrent inability to achieve or maintain sufficient sexual excitement, causing personal distress. It may be expressed as a lack of excitement or a lack of genital (lubrication/swelling) or other somatic responses.
- Orgasmic disorder is the persistent or recurrent difficulty, delay, or absence of attaining orgasm following sufficient sexual stimulation and arousal, and causes personal distress. This may be a primary (never achieved orgasm) or secondary condition, as a result of surgery, trauma, or hormone deficiencies.
- Sexual pain disorder includes dyspareunia (genital pain associated with sexual intercourse); vaginismus (involuntary spasm of the vaginal musculature that causes interference with vaginal penetration), and noncoital sexual pain disorder (genital pain induced by noncoital sexual stimulation).

Each of these definitions has three additional subtypes: lifelong versus acquired; generalized versus situational; and of organic, psychogenic, mixed, and unknown etiological origin.

In 2004, the Second International Consensus of Sexual Medicine accepted revised definitions of female sexual dysfunction, as given in Table 104.1.<sup>33</sup>

## Causes of Women's Sexual Dysfunction

The basis of desire and perceived arousal in women is poorly understood, but it appears to involve interactions among multiple neurotransmitters, sex hormones, and environmental factors.<sup>34</sup>

Many medical conditions contribute to women's sexual dysfunction (see Table 104.2).<sup>35–38</sup> The microvascular complication may lead to decreased blood flow to the genitalia, causing decreased arousal and delayed orgasm, while polyneuropathy may also contribute to the problem. Arthritis may make intercourse uncomfortable and even painful. It is essential to aggressively treat these conditions and inform the patients of how they can affect sexuality.

There also are various gynecologic causes of women's sexual dysfunction, contributing to physical, psychological, and sexual difficulties, given in Table 104.3.<sup>39,40</sup> The hormonal change during pregnancy/postpartum period may lead to a decrease in sexual activity, desire, and satisfaction, which may be prolonged by lactation. Gynecological surgery such as hysterectomy or vulvar

**Table 104.1:** Revised Definition for Female Sexual Dysfunction from the Second International Consensus of Sexual Medicine

<b>Sexual desire/interest disorder:</b> absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies, and a lack of responsive desire; motivations for attempting to become sexually aroused are scarce or absent; lack of interest is considered to be beyond the normal decrease experienced with increasing age and relationship duration
<b>Subjective sexual arousal disorder:</b> absent or diminished feelings of sexual arousal from any type of sexual stimulation; however, vaginal lubrication or other signs of physical response occur
<b>Genital sexual arousal disorder:</b> complaints of impaired genital sexual arousal, which may include minimal vulvar swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia; however, subjective sexual excitement occurs with nongenital sexual stimuli
<b>Combined genital and subjective arousal disorder:</b> absent or diminished feelings of sexual arousal from any type of sexual stimuli plus complaints of absent or impaired genital sexual arousal
<b>Persistent genital arousal disorder:</b> spontaneous, intrusive, and unwanted genital arousal in the absence of sexual interest and desire; arousal is unrelieved by orgasms and persists for hours or days
<b>Orgasmic disorder:</b> despite self-report of high sexual arousal or excitement, there is lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation
<b>Dyspareunia:</b> persistent or recurrent pain with attempted or completed vaginal entry and/or penile-vaginal intercourse
<b>Vaginismus:</b> persistent or recurrent difficulties with vaginal entry of a penis, finger, or other object, despite the woman's expressed desire to participate
<b>Sexual aversion disorder:</b> extreme anxiety or disgust at the anticipation of or attempt at any sexual activity

**Table 104.2:** Medical Etiology of Women's Sexual Dysfunction

<b>Endocrine</b>	Addison disease, adrenal disorders, Cushing syndrome, decreased estrogen and testosterone, diabetes, prolactinoma, thyroid disease
<b>Gastrointestinal</b>	Irritable bowel
<b>Neurologic</b>	Childhood trauma, epilepsy, head injuries, multiple sclerosis, neuropathies, Parkinson disease, spinal injury, stroke
<b>Psychological</b>	Anxiety, emotional trauma, depression, intra- or interpersonal conflicts, life stressors, physical or sexual abuse
<b>Respiratory</b>	Chronic obstructive pulmonary disease
<b>Rheumatologic</b>	Arthritis, autoimmune disorders, fibromyalgia
<b>Surgical</b>	Colostomy, pelvic surgery
<b>Urinary</b>	Renal failure
<b>Vascular</b>	Coronary artery disease, hypertension, myocardial infarction, pelvic surgery, pelvic trauma, peripheral vascular disease

**Table 104.3:** Gynecological Etiology of Women's Sexual Dysfunction

<b>External genitalia</b>	Bartholin duct cysts, Bartholinitis, Bartholin abscess, clitoral adhesions, episiotomy scar, dermatological lesions (dermatitis, lichen sclerosis, vulvar cancer, vulvar dystrophy), herpes genitalis
<b>Internal genitalia</b>	Atrophic change, cancer, chronic pelvic pain syndrome, cystocele/rectocele, endometriosis, pelvic inflammatory disease, uterine prolapse, uterine fibroid, vaginismus, vaginitis

**Table 104.4:** Medications Likely to Result in Women's Sexual Dysfunction

Antihypertensives	Benazepril, clonidine, lisinopril, methyl dopa, metoprolol, propranolol, reserpine, spironolactone, timolol
Antidepressants	Amoxapine, bupropion, fluoxetine, imipramine, clomipramine, paroxetine, phenelzine, sertraline, trazodone, venlafaxine
Anxiolytics	Buspirone, alprazolam, clonazepam, diazepam, lorazepam
Illicit and abused drugs	Alcohol, amphetamines, amyl nitrate, barbiturates, cocaine, marijuana, ecstasy, methyl-methylenedioxym-amphetamine, morphine, tobacco
Miscellaneous Antipsychotics and mood stabilizers	Acetazolamide, amiodarone, bromocriptine, cimetidine, danazol, digoxin, diphenhydramine, ethinyl estradiol, gemfibrozil, medroxyprogesterone acetate, metronidazole, niacin, phenytoin, ranitidine, perphenazine, prochlorperazine Phenothiazines, Lithium

excision may cause a loss of a psychological symbol of femininity and lead to decreased sexuality. It is important to appropriately treat these conditions and inform the patients of how they may be affected sexually.

Details of medication both prescription and over the counter, as in Table 104.4, should be obtained in order to identify any contributing agents.<sup>41,42</sup> Consideration should be given to dose adjustment, drug alteration, and even drug discontinuation. In addition, use of recreational drugs, alcohol, and alternative therapies should be discussed.

**Assessment:** Involves considerable sensitivity and skill on the part of the physician. It should gradually move from initial phase of screening to a more specific in-depth enquiry exploring into various types of sexual disorders.

## Sexual History Taking

### SCREENING QUESTIONS

The history taking should begin with non-threatening questions. Various examples of questions related to screening

sexual history are:

- Are you currently sexually active? If yes,
- Do you have any discomfort or other problem or any difficulty achieving orgasm? If yes, does this bother you?
- Do you ever experience pain during intercourse?
- Do you have any questions or concerns about your sexual functioning? About your partner's sexual functioning?
- Does that bother you or your partner?

### SPECIFIC SEXUAL HISTORY

Where the patient presents with a specific sexual problem, such as a possible sexual dysfunction or has questions/concerns about sexual functioning, a specific sexual history should be taken appropriate to the problem and concern. Those include history of STI/HIV/AIDS, menstrual, obstetric, perimenopausal, sexual relationship, sexual behavior, and about sexual intercourse etc. The specific sexual history can be explored in depth, and tailored to suit relevant problems such as desire disorder, arousal disorder, lubrication and penetration, and orgasmic disorder.

The several types of sexual problems/queries comprise of:

- (1) myths and misconceptions,
- (2) fear,
- (3) deeper insecurities,
- (4) sexuality in health and diseases,
- (5) sex after surgery,
- (6) alternative orientations, and
- (7) difficult situations.

In addition, two vital questions are suggested at the end of each subset to clarify to the patient, and reminding the neglected point.

- What do you attribute your problem to?
- Is there anything which I have not asked but you would like to tell?

### DESIRE DISORDER HISTORY

Several female reproductive life experiences may uniquely affect sexual desire. These events include menstrual cycles, hormonal contraceptives, postpartum states and lactation, oophorectomy and hysterectomy, and perimenopausal and postmenopausal states.<sup>43</sup> Desire disorder is associated with a wide variety of medical and psychological causes.<sup>44</sup> Questions to ask about desire disorder, (adapted from Ross)<sup>45</sup> are:

- How often do you have sexual intercourse?
- How long have you had the loss of desire?
- How is this problem affecting you? Are you concerned or bothered by it?
- How is your loss of desire affecting your relationship?
- Is it always a problem? Is it a problem only at certain times or in certain situations?
- Has the problem changed over time? If so, how?
- Does anything appear to improve your libido or make it worse?

- Does your partner have any sexual difficulties?
- Do you have any idea about what may be causing your loss of desire? How about your partner's reaction?
- Have you seen anyone else about this problem? If so, what was suggested? What steps were taken?
- Is there anything in your current situation that makes sex unpleasant or difficult with you?

## AROUSAL DISORDER HISTORY

Questions to ask about desire disorder, (adapted from Ross)<sup>45</sup> are:

- How often do you have sexual intercourse?
- How do you and your partner initiate intercourse?
- Do you and your partner usually welcome the idea?
- What happens during foreplay?
- How you feel when your partner inserts his penis?
- Do you touch yourself?
- Have you had any unpleasant experiences with sex?
- Is there anything in your current situation that makes sex unpleasant or difficult with you?

## LUBRICANT AND PENETRATION DISORDER HISTORY

Pain on vaginal penetration for intercourse is a common primary symptom. Questions to ask with regards to lubrication and penetration disorder, (adapted from Ross)<sup>45</sup> are:

- How often do you have sexual intercourse?
- Do you and your partner start with foreplay? How long? Long enough?
- Do you begin to lubricate during foreplay?
- Do you have painful penetration?
- Is penetration successful?
- Is your partner's penis able to remain stiff for insertion? Loses stiffness?
- How do you feel when you or your partner starts the pelvic movement?
- How does your partner feel about your response?

## ORGASMIC DISORDER HISTORY

Orgasmic disorder is parallel in both men and women; it includes early orgasm, delayed orgasm, impaired orgasm, and absence of orgasm. Questions to ask about orgasmic disorder, (adapted from Ross)<sup>45</sup> are:

- Tell me what happened the first time you had sexual intercourse.
- Have you had any unpleasant experiences with sex?
- How did you feel about it at that time?
- What were your physical responses?
- Tell me about your experiences after that.
- How often do you have sexual intercourse?
- What features of the act are you interested in?
- Do you have any problems with lubrication?
- Do you touch yourself?

- How long do you and your partner use for foreplay? Does it satisfy you?
- After you admit the penetration, about how long does it take before you achieve orgasm?
- How do you feel during pelvic movement? Active or passive role?
- How do you feel after sexual intercourse?

There are two common reasons why these questions are not often asked. First, because the clinician may feel uncomfortable with the questions or with his or her level of knowledge of the subject and, second, the amount of time needed for enquiry once the patient senses sincere interest and feels comfortable in beginning a dialogue with the provider. Presence of the partner may also be useful later, once the patient has covered her own concerns.

## Laboratory Testing

With aging, both estrogen and androgen levels decrease in the female, resulting in an increase in sexual pain problems and diminished libido. Although no specific laboratory tests are universally recommended for the diagnosis of women's sexual dysfunction, routine Pap smear and stool examination should not be overlooked. Baseline hormonal profile may be helpful when indicated, including thyroid-stimulating hormone, follicle stimulating hormone (FSH), luteinizing hormone (LH), total and free testosterone, sex-hormone-binding globulin (SHBG), estradiol, and prolactin. FSH and LH can be helpful in assessment of primary and secondary hypogonadism, while decreased estrogen can lead to decreased libido, vaginal dryness and dyspareunia, and testosterone deficiency, as well as raised prolactin, can also cause decreased libido, arousal and tactile sensation. The SHBG level increases with age, and free estrogen level decreases.<sup>46</sup>

## Diagnosis and Management

Women's sexual dysfunction is multifactorial, often with several different etiologic causes contributing to the problem. However, the careful assessment and available treatments can improve the sexual well-being for many women. The diagnosis of women's sexual dysfunction requires the physician to obtain a detailed patient history that defines the dysfunction, identifies causative or confounding medical or gynecologic conditions, elicits psychosocial information, and assesses the patient's goal to set realistic patient expectation, before starting therapy.<sup>47</sup>

Many medical, gynecological, medication, and psychological etiologies are associated with sexual difficulties and problems, which are often underreported and under diagnosed. The patients may feel that sexual problems in the context of disease are not important enough to be mentioned to their physicians, and physicians may feel uncomfortable and sometimes incompetent. Sometimes a sexual problem can be easily improved by diagnosing and treating an underlying problem, such as changing medication use, and treatment of substance abuse. While the complex or multiple aspects of sexual problems can be time intensive, they require specialists (cardiologist, psychiatrist, psychotherapist, sex

therapist, and pelvic physical therapist) with a team approach. In addition, for women with a regular partner(s), the partner needs to be involved in the management of sexual dysfunction.

### Non-Pharmacologic Therapies

The non-pharmacologic options should be the initial treatment for the majority of women because all currently available pharmacologic therapies are of limited efficacy and are associated with potential side effects. The primary focus of the treatment should be confined to optimize health, well-being, and interpersonal relationships.

Some of the non-pharmacological therapies that have been found to be useful are given below:

### Counseling

It is important to counsel that the frequency of sexual activity is not necessarily correlated with sexual satisfaction. Sexual dysfunction only becomes a difficulty when the patient and/or her partner find it to be a problem. Psychological counseling can also play a vital part in treating some women who suffer from female sexual dysfunction, whereas clinical and educational counseling can benefit women in such areas as normal anatomy, the wide variation of the physiologic basis of sexual functioning, coaching in sexual stimulation techniques (foreplay), and the integration of general sexological and disease-specific dimensions. The couple's counseling is effective when there is interpersonal relationship conflict or limited communication.

The counseling could differentiate three diagnostic dimensions. The first are person-related pre-existing factors, such as sexual satisfaction and function, age, body image, and general well-being. The second are the disease-specific implications, which could be summarized under the 8 Ds:

- Danger
- Destruction
- Disfigurement
- Disability and pain
- Dysfunction
- Dysregulation
- Disease load
- Drugs

The third is the patient's and partner's general response to the disease determined by affective response, coping style, body image impact, and changes in relationship dynamics. The differentiation helps the physician to evaluate sexual problems of the female patients with specific clinical conditions in order to facilitate access to recognition and possible treatment.<sup>48</sup>

### Non-coital Behaviors

These include sensual massage and sensate focus exercises. The sensate focus exercise program consists of touching, stroking, kissing, embracing, caressing, and sensual massage during non-

coital love play in ways that are mutually gratifying, first described by Masters and Johnson.<sup>11</sup> It can be used in conjunction with other therapy options such as medication, vacuum devices, etc. The couples allow approximately 30–60 minutes daily (or several times a week) of love play sessions.

Sensate focus may also be used by couples who are not experiencing sexual dysfunction but who want to enhance their sexual relationship. Emphasis is not placed on performance, but on the feelings and sensations of each partner who assumes the active and passive roles at different times during the session. This technique allows patients to know and understand each other's bodies and can be highly effective.

There are several stages associated with sensate focus, according to Masters and Johnson,<sup>49</sup> and as described by Ramage.<sup>50</sup> In the first phase, each explores the other's body without touching the genitals and breasts. The second phase additionally allows exploring genitals and breasts, but intercourse is still forbidden. Focus may be put on different types of touching and stroking of the genitals and the sensations associated with this. Mutual masturbation resulting in orgasm may be an option at this phase of sensate focus. Intercourse is permissible during the final stage of sensate focus exercise, which may start from penetration without thrusting, gentle thrusting or rotating, and thrusting to the point of orgasm. Couples have to consent and agree on the rate of progression through the stages and levels of the sensate focus exercise. It is still crucial for the couple to continue with mutually satisfying love play prior to and during intercourse.

On subsequent occasions, genital touching is allowed, but orgasm is not the goal. Indeed, the goal of sensate focus is to help the partners learn to give and receive pleasure by promoting trust and communication and by reducing anxiety related to sexual performance.

### Kegel Exercises

Kegel exercises, named after Dr. Arnold Kegel, and originally developed in 1948, are exercises of the pubococcygeus muscles which are a major musculature of the levator ani (pubococcygeus, puborectalis and iliococcygeus muscle). This exercise is a method of controlling incontinence in women following childbirth, and now is widely recommended for women with urinary stress incontinence, some men who have urinary incontinence after prostate surgery, as well as people who have fecal (stool) incontinence.

The exercise involves the regular contraction and relaxation of the pelvic floor muscles and is designed to restore muscle tone, reduce overactive bladder symptoms, and to increase sexual satisfaction.<sup>51</sup>

The pelvic floor muscles attach from the pubic bone anteriorly to the coccyx posteriorly and form a bowl-like structure, along with ligaments and fascial tissue. The main functions of the pelvic floor are to provide support for the pelvic organs and prevent incontinence by promoting voluntary closure of the urethral and anal sphincters. Adequate pelvic floor muscle function is a necessary component of bowel and bladder control.

The pelvic floor muscles have been proposed to be active in genital arousal and orgasm in both genders, while their hypotonus may impact negatively on these phases of sexual function.<sup>52</sup>

The strong pelvic floor muscles in women, particularly the ischiocavernosus muscle that attaches to the clitoral hood, are crucial for adequate genital arousal and attainment of orgasm,<sup>53</sup> however, weak or de-conditioned muscles may provide insufficient activity necessary for vaginal friction or blood flow, and inhibit orgasmic potential.<sup>51</sup>

The starting point is aimed at building pelvic floor strength. However, some people have difficulty identifying and isolating the muscles of the pelvic floor. Care must be taken to learn to contract the correct muscles. Typically, most people contract the abdominal or thigh muscles, while not even working the pelvic floor muscles. These incorrect contractions may even worsen pelvic floor tone and incontinence.

#### How to do Kegel exercises?

- Locate the pelvic muscles by stopping the flow of urine mid-stream, and learn how to contract and relax them
- Contract for 1 second and then release, and gradually increase up to 3, 5, and 10 minutes of contractions, 3, 5, and 10 times in a row, and 3, 5, and 10 times a day, respectively
- Doing exercises with a full bladder or while emptying the bladder can actually weaken the muscles, and also lead to incomplete bladder emptying, which increases the risk of a urinary tract infection.

Recently, hypertonus has been found to be a significant contributor to the mechanism of chronic pelvic pain and associated sexual dysfunction. This condition needs physical therapy treatment as an integral component of a multidisciplinary approach.<sup>54</sup>

#### Eros-Clitoral Therapy Device

The Eros clitoral therapy device is approved by US FDA for the treatment of women with sexual arousal disorder. The simple mechanism involves inducing specific clitoral erection using vacuum therapy by self erection inducer device. Therapy over a 6-week period has been shown to be safe and effective in improving symptoms of female sexual arousal, and for enhancing the ability to experience orgasm as assessed by the Female Intervention Efficacy Index,<sup>55</sup> as well as by significantly increasing clitoral and corpus spongiosum diameter, and peak systolic and end-diastolic velocity values, using duplex Doppler ultrasonographic study.<sup>56</sup>

#### PHARMACOLOGIC THERAPIES

The use of pharmacologic therapy should be restricted to women who meet the diagnostic criteria for a sexual disorder, in the form of a sexual problem associated with personal concern, and for whom non-pharmacologic schemes have been demonstrated to be ineffective. Treatment options focus on providing hormonal support and increasing genital blood flow. However, there is no single intervention leading to adequate treatment of women's sexual dysfunction. For example, optimal treatment of diminished

sexual desire may necessitate not only androgen use, but also couple counseling.

#### Estrogen

The mechanism of estrogen's effect on desire is indirect and occurs through improvement in urogenital atrophy, vasomotor symptoms and menopausal mood disorders. This relationship helps predict which patients are likely to respond to estrogen and/or estrogen and progesterone replacement therapy (conjugated equine estrogen 0.625 mg and medroxyprogesterone acetate 2.5 mg daily) in those with symptoms of hypoestrogenism, and may explain why some studies do not show estrogen-mediated improvement in sexual functioning.<sup>57</sup> Hormone treatment did not significantly alter mood ratings, sexual behaviors, or psychophysiological measured sexual arousal.

#### Progesterone

A potent progesterone, such as medroxyprogesterone acetate, is necessary for women with an intact uterus using estrogen; however, it may negatively affect mood and contribute to decreased sexual desire. Monophasic estrogen-progestin therapy in postmenopausal women has a beneficial effect not only on hot flush and atrophic vaginitis but also on sexuality improvement such as sexual desire, dyspareunia, and satisfaction with the duration of penetration.<sup>58</sup>

#### Tibolone

Tibolone is taken orally in the dose of 2.5 mg daily, its metabolites have estrogenic, androgenic, and progestational effects. A small placebo controlled trial in postmenopausal women found tibolone increased vaginal lubrication, arousability, and sexual desire, but did not change frequency of sexual intercourse or orgasm compared to placebo. Tibolone is also effective for the management of osteoporosis, but may be associated with an increased risk of breast and endometrial cancer.<sup>59</sup>

#### Androgen

The 300-microgram per day testosterone patch for 24 weeks increased sexual desire and frequency of satisfying sexual activity and was well-tolerated in women who developed hypoactive sexual desire disorder after surgical menopause.<sup>60,61</sup> One study showed a statistically significant increase in facial hair.<sup>62</sup>

Testosterone in another form, testosterone 1% cream, 10 mg daily for 12 weeks, applied to the thigh also improved sexual self-rating scores by 50% or greater in a statistically greater number of women receiving testosterone compared with placebo.<sup>63</sup>

#### L-arginine

L-arginine, an amino acid, has been touted as the natural Viagra due to the claimed ability to release nitric oxide, causing increased vasocongestion in the genitalia of both sexes. More studies are necessary before conclusions can be drawn regarding any of these products.

Future therapies—a number of products are under research and development for use in women with sexual dysfunction.<sup>64,65</sup>

## Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors (sildenafil, tadalafil, vardenafil) involve adrenergic and/or nitric oxide systems. Sexual stimulation leads to nitric oxide production that in turn stimulates the release of guanylate cyclase which converts guanosine triphosphate to cyclic guanosine monophosphate (cGMP). The cGMP produces relaxation of the smooth muscles of the penile arteries and corpus cavernosum, resulting in increased blood flow into the penis.

These drugs inhibit the metabolism of cGMP, thus prolonging its action. Some evidence suggests that a comparable event may occur in women, as the anatomy of the clitoris is similar to that of the penis. Results from a limited number of placebo controlled studies suggest that the phosphodiesterase inhibitor sildenafil in various doses increases arousal, enjoyment, satisfaction, frequency of intercourse, and sexual fantasies compared with placebo, as well as improving genital sensation, vaginal lubrication, satisfaction with intercourse, and clitoral sensitivity, particularly among postmenopausal women with sexual dysfunction.<sup>66–69</sup>

## Alprostadil

A randomized, placebo-controlled, crossover design study evaluated the effects of alprostadil for the treatment of female sexual arousal disorder. The study compared topical alprostadil solution and placebo, applied to the external genitalia and followed by 30 minutes of visual sexual stimulation. Genital vasocongestion, and physical and sexual satisfaction, were significantly greater than placebo with the 400 microgram dose, but not with the 100 microgram dose. The most common adverse event was mild, transient genital burning typically of less than 1-minute duration.<sup>70</sup>

## Minimizing Sexual Pain

The sexual pain syndrome includes dyspareunia and vaginismus. The alleviation of superficial dyspareunia is the specific treatment of the underlying cause, the use of lubricants, and distraction techniques such as encouraging erotic or nonerotic fantasy, and pelvic muscle contraction and relaxation exercises with intercourse. The management of vaginal dyspareunia is the same as for superficial dyspareunia, whereas the management of deep dyspareunia comprises positional changes so that force is directed away from pain and deep thrusts are minimized, and nonsteroidal anti-inflammatory drugs may also be used before intercourse. However, underlying conditions such as endometriosis, interstitial cystitis, adnexal and bowel pathology should be considered.<sup>71</sup>

Vaginismus is the involuntary contraction of the muscles of the outer one-third of the vagina, and often related to sexual phobias or past abuse or trauma. It can be complete or situational, so that a pelvic examination might be possible while intercourse is not. Vaginismus has a strong psychological component that should be

addressed for successful treatment. Therapy for and counseling of women with vaginismus consists of progressive muscle relaxation and vaginal dilatation with commercial dilators or tampons of increasing diameter placed into the vagina for 15 minutes twice daily. Once the patient can easily accept an equivalent-sized dilator into the vagina, penile penetration by the partner can occur.<sup>39</sup> Success rates approach 90%.<sup>72</sup>

Vulvodynia or vulvar pain syndrome is a chronic, heterogeneous, and multifactorial disease with a high prevalence. This condition typically affects older women while vestibulitis is localized pain provoked by penetration in younger women. The etiology of this condition is complex and remains elusive. An accurate diagnosis requires a comprehensive history, physical examination and targeted diagnostic tests. Although many treatment options have been utilized, a rational therapeutic strategy is still under research. Psychological counseling and group support should be considered in all cases.<sup>73</sup>

## Conclusion

Women's sexual dysfunction is a condition of complexity in both diagnosis and treatment. Numerous women suffer from sexual dysfunction; however, it is unknown how many women are successfully treated. Though there is no permanent cure, all kinds of sexual dysfunction can be controlled and improved with treatment. To date, there are no pharmacological agents proven to be beneficial beyond placebo in enhancing orgasmic function in women. Until recently, there has been limited clinical or scientific research in the field of sexual dysfunction in women. Although some progress has been made, additional research is needed to assess treatment efficacy and establish standard treatment guidelines.

### Is Sexuality Education Necessary?

Children are naturally curious about sex and bodies but frequently get a message very early in life that this is not an area in which questions are welcomed or where they will get honest and clear answers. Research with Australian parents has indicated that they believe they are communicating well with their children<sup>1</sup> and are keen to provide information. At the same time parents are also wishing to give moral and safety messages<sup>2</sup> in the face of a perceived tidal wave of conflicting sexual values. Education from parents can also be complicated by the embarrassment experienced by many adults in discussing an area which is sensitive or taboo. In many cases, parents have grown up in times when families did not talk about sexuality, and they now want to do things differently. It is therefore not surprising that many young people grow up without getting reliable factual information, or an opportunity to reflect on managing sexuality related issues supported by adults close to them. In the past this might have meant that they remained ignorant, with all the potential for danger that entailed, but today young people have so many other sources of sexual messages and information that this is not likely to be the case. Internet sites, advertising, film and television, as well as the ever-present option of sharing knowledge among peers, means that young people learn a lot about sex, and more than ever need support and guidance to make sense of it all.

Good sexuality education is far more than just imparting knowledge and making sure young people have factual information if we are to prepare them for safe and enjoyable adult sexual lives.<sup>3</sup> The cognitive development of young people throughout adolescence means that they are progressively less willing to accept what their parents tell them is right or wrong. At this stage of life they prepare for adulthood by canvassing the views of many others, especially peers, in order to develop a personal ethic and make sound decisions for themselves. The World Health Organization (1998) has set a broad agenda of the life skills needed for young people to maintain their sexual health. These are the ability to:

- make sound decisions about relationships and sexual intercourse and stand up for those decisions

- deal with pressures for unwanted sex or drug use
- recognize a situation which may turn risky or violent
- know how and where to ask for help and support
- know how to negotiate protected sex and other forms of safe sex when ready for sexual relationships

Detailed knowledge about human anatomy and physiological changes or various sexually transmitted infections is only a small part of the learning that young people need to put such skills in place. Yet, too often it is the factual knowledge that is seen to stand alone as “sexuality education” because some of the other areas are too challenging for parents and teachers alike.

### Partnerships—Who should be Involved in Sexuality Education?

Parents and caregivers are the first teachers of children learning about sexual development and relationships. Even if no formal education takes place, they are role models for their children and inevitably convey messages about the acceptability and appropriateness of ideas and behaviors. However, actual discussions that answer children’s questions honestly and factually from an early age provide an important foundation for ongoing education. As children move into adolescence, those parents who have established good communication with their children have an opportunity to put their views and values in a way that young people perceive as non-authoritarian and therefore valuable. Parents and caregivers can also play a role in assisting young people to find other reliable and independent sources of help such as introducing them to a good medical service. Whatever they are able to contribute to the sexual development and decision making of their growing child is extremely important. The lessons learnt about relationships and the sources of support found within the family may also have a strong influence on the adolescent’s drift towards a particular peer group,<sup>4</sup> which leads us to what is likely to be the second greatest determining factor of an adolescent’s sexual choices, their peers.

Peers are an inevitable source of information for young people and are a readily available one which they experience as being

trustworthy and accessible.<sup>5</sup> Peers also act as the standard setters for what are deemed to be acceptable sexual behaviors and conduct of relationships, as acceptance and connection with peers are highly prized by the developing adolescent. While information that they have may be limited or incomplete, their genuine empathy for their fellows and their ability to offer realistic advice and support can be valuable assets.<sup>6</sup> Many educators despair of young people privileging information from peers over that given by more authoritative sources. As we educate young people in schools we are also educating peers who have the capacity to remain supportive. Peer education programs recognize this resource and can capitalize well on their credibility.<sup>7</sup>

While home and peers remain the most influential spheres of influence in a young person's social and sexual lives, school then becomes an essential third partner with a different and important role to play. School-based education ensures there is a place for guided discussion and critical reflection about sexual choices, skills practice and situation rehearsals, hearing others' views and decision-making processes, and critiquing and understanding the range of influences.

Also involved in sex education for young people may be healthcare professionals who have expert knowledge of some key curriculum areas and also have the ability to encourage young people to seek medical advice when it is needed. Healthcare professionals have been generally used in an ad hoc way in schools<sup>8</sup> with misunderstandings on both sides about how much of the curriculum they should teach. Their most valuable contribution to school-based programs is enabling young people to meet a local nurse or doctor in the safe environment of a classroom. This is likely to make it easier for young people to follow-up the contact individually when the need arises. Outside agencies taking classroom lessons should be limited as they cannot replace trained and committed teachers who have an ongoing relationship with their students in teaching the entire curriculum.

The fourth potential member of the partnership in some cases may be the church which would take a role in contributing to education in the moral aspects of sexual decision making and behavior. While for many this moral dimension would be seen as a religious one, other young people develop a personal morality from many alternative sources of which the church may only be one.

## What is Good Sexuality Education?

The value of comprehensive sexuality education in schools should no longer be a matter of debate. While young people attend school they present an opportunity for education that will not be there at a later stage when they are out in the workforce and the evidence that sexuality education works is now very strong. In December 2009, the United Nations Educational, Scientific, and Cultural Organisation released the final version of their *International Guidelines on Sexuality Education*. The guidelines are in two parts and the first covers the evidence base for this work with a review of 87 program evaluations that the authors deemed

comparable and that had documented demonstrated effects on the sexual behavior of participants. Additional 11 studies of abstinence-only school programs were analyzed separately.

Of the 87 core projects from all over the world, more than a third were found to delay the initiation of intercourse, about a third decreased the frequency of intercourse, more than a third decreased the number of sexual partners, and nearly all studies demonstrated an increase in knowledge. There was very strong evidence that more than one third of the programs increased condom or contraceptive use and that more than half reduced sexual risk taking. The abstinence-only programs however, were less successful with only two showing any evidence of delaying sexual intercourse or reducing the frequency of sex, and one reducing the number of sexual partners. It is clear that sexuality education, if it is carried out in particular ways, can make a difference to the safety and wellbeing of young people.

The evidence drawn from this meta-evaluation is used in the second part of the guidelines to distil four elements of best practice. These are the key elements that are commonly found accompanying measurable improvement in student knowledge and behavior, and the ones that most deserve our attention and advocacy to preserve an area of education which is often contested or under threat.

The first two elements are connected and are probably the most challenging for those working in a school setting because they are about time allocation. Good programs require at least 12 sessions and need to be sequential over several years. It is well-established that young people go through puberty on differing timetables and that they become sexually active at different times.<sup>9-11</sup> Covering this range of needs takes time and persistence but is important if young people are to have access to education when they most need it.

The third element of best practice is outside the classroom and requires the support of, and supervision by, school managers. A whole school commitment to the values that privilege sexuality education as essential for young people requires strong and committed leadership. It cannot be just the work of one passionate teacher who may face criticism from outside sources. Teachers move on for various reasons and it is important that schools maintain a consistent program over time that is part of the regular curriculum. To encourage school leadership to support such programs it may be vital to have a centralized strong government policy which leaves individual schools in little doubt about their responsibility to educate the young people in their care. It can be difficult for individual schools to take a stand and face possible public criticism without the clear authority that a government policy brings.

The final element of best practice is about teachers. Essential to the conduct of best practice sexuality education are capable and motivated teachers who receive quality training. Many times sexuality education is not seen as a prestigious area of education and, despite its importance in the lives of pupils, it is given to a reluctant teacher who is asked to do this work without being trained to do so. Good teacher training is essential to make teachers confident, not just in their knowledge, but in using the

discussion-based methods that help students formulate ideas and develop new skills.

These guidelines also map the territory of good sexuality education to provide a sound basis for curriculum development and classroom planning. The content areas are:

- Relationships, including those with families and friends as precursors to romantic relationships, long-term commitment, marriage, and parenting.
- Values, attitudes and skills, including norms and peer influences, decision making and refusal and negotiation skills.
- Culture, society, and human rights, including the role of the media and gender-based violence and other harmful practices.
- Human development which covers not just anatomy and physiology but also reproduction, the changes of puberty, body image, and bodily integrity.
- Sexual behavior and responses across the life cycle.
- Sexual and reproductive health, including pregnancy and sexually transmitted infection (STI) prevention.

A program which picks up elements of all these areas, begins early, is carried out in a sustained manner and is practical and non-judgmental in its approach will serve young people well.

### What is Age-Appropriate Sexuality Education?

Not all elements of a comprehensive program will be taught at all levels of a child's development and most will be adapted to what children can understand. For example, the area of relationships will focus on family and friends in the early years and move to romantic relationships as that interest develops in the growing adolescent. Age-appropriate sexuality education is education that is relevant to the individual student's physical and cognitive development at the time.<sup>3</sup> Identifying what is age appropriate brings challenges. Not all students of any given age are the same. In any classroom there will be a wide range in the students' growth, interests, and needs, despite sharing the same age. Additionally, child and adolescent sexual development is not wholly biologically determined. As much as bodily growth imposes a general guide of what young people will need, the types of information and skills they need are also influenced by the social context, time, and place in which they live. There is no "universal" 12-year-old or 16-year-old, with corresponding universal educational needs. This is an area where lifelong learning will be as important as anything learnt in school.

That said, programs must attempt to gauge students' needs and concerns to inform any program's content and teaching methods and acknowledge and respond to cultural differences. This needs assessment process, an ongoing one by the teacher who may use methods such as anonymous question box, classroom discussion to assess students' maturity, brainstorm activities around the meaning of different words, and personal one-to-one discussions.

### Respecting Cultural and Religious Diversity

Being respectful of cultural and religious differences should not override a basic assumption that there is some core educational territory which must be covered for all young people.<sup>3</sup> When any of this basic information seems to be in conflict with the cultural or religious beliefs of some students, then it is important to find ways of teaching that address some of those concerns.

Addressing these issues may take many forms. Reassurances about the research evidence showing that sexuality education does not lead to increased sexual activity<sup>12</sup> are valuable. So is information about the broad nature of sexuality education beyond just sexual intercourse to relationships, decision making, and other health issues. Sometimes a person with health or religious expertise may be the best person to present some material. Single sex groups may also make education in sensitive areas a bit more comfortable.

Students may need to be reminded that while everybody is entitled to their own set of values and debate them respectfully in a constructive way, values and beliefs which compromise the safety and wellbeing of other students should not be expressed within a classroom. Homophobic, racist, or sexist remarks should never be tolerated in a sexuality education classroom.

### Respecting Sexual Diversity

Research has shown that around 10% of young people experience same sex attraction, often while they are at school.<sup>13,14</sup> While this does not automatically indicate any particular sexual identity, all of these young people are struggling with a possibility which they may be reluctant to share with anyone else for fear of rejection. Same-sex attracted young people experience high levels of stigmatization, violence, and abuse, particularly in schools.<sup>13-15</sup> It is not a safe strategy to assume that as a teacher you can identify young people in this category and develop education based on their needs.

All young people need to hear positive and reassuring messages about homosexuality as a natural and healthy way for some people to be, and to have inclusive messages built into all areas of the curriculum. For example, if the issue of STI transmission is being covered then discussing it in terms of specific sexual practices rather than as "intercourse between a man and a woman" would be an inclusive message. Another way to be inclusive is to use the term "partner" in discussions about relationships so that everybody can experience their issues being reflected in the discussion.

### Respecting Young People with a Disability

All children and young people need sexuality education. Some students, depending on the type of disability, will require even more efforts to ensure their reliable sexual learning. In the past, a degree of protectiveness around students with disabilities may have meant curtailing opportunities for exploring this side of their development. For example, even though people with an

intellectual disability can experience STIs, unplanned pregnancy, and sexual abuse at higher rates than the rest of the population, they do not always have the opportunity to learn protective behaviors. Students with learning disabilities should still receive information that is relevant to their age, for example, information about puberty, however, the teaching methods may need to vary to accommodate the disability. The goal should always be to find an appropriate way to ensure these students are not excluded from sexuality education.

## A Holistic Approach

Young people will educate themselves about sexual matters irrespective of whether or not they receive formal education. They live in social worlds that give them access to information in far greater volumes than in the past. The issue of accessing age-appropriate and authoritative sexuality education has now become one of human rights.<sup>16</sup> Whole schools can work together outside classroom lessons to teach and reinforce respectful relationships between the sexes and positive role modeling around respectful and appropriate language and behavior. This gives students an excellent grounding for safe and satisfying adult relationships in the future. Peer groups which are well-informed and well-supported play a key role in a cohort of emerging adults who in turn support one another. Families which see the territory of sexuality education as one for informal discussion and lifelong learning also contribute well to the development of young people. Sexuality is more than a range of behaviors and a body of knowledge. It is a core part of being human and is best nurtured by a range of partners who can make a unique contribution to the future of a young person.

## Introduction

In most cultures, sexual adequacy is the benchmark of masculinity, virility, personal adequacy, and fulfillment.<sup>1</sup> Semen loss related psychological distress has been reported consistently, both in European as well as Asian cultures. While Ayurveda cautions against the loss of semen and argues for its conservation, in the West emphasis has been on defining the adverse physical and psychological sequelae of seminal loss. Dhat syndrome, a term coined by Wig<sup>2</sup> is deemed to be a common culture-bound preoccupation regarding semen loss among patients in the Indian subcontinent. This condition, strictly speaking, is not a psychosexual dysfunction but a culture-specific, sex-related disorder.<sup>3</sup> The presented symptoms in this syndrome have a hypochondriac quality and usually include general weakness, lack of energy and concentration, impaired sexual functions, and vague somatic troubles, all associated with an anxious and dysphoric mood state; typically attributed to the imagined loss of semen in urine or to natural nocturnal emissions.<sup>4</sup> Despite the patient's assertion and concern about the passage of semen in urine, there is no objective evidence of presence of semen in the urine.<sup>5</sup>

## Evolution of Concept

Ayurveda system teaches the physiology of the production of semen, based on the central idea that there are seven essential constituents of the body (the seven *Dhatus*: chyle, bile, blood, flesh, fat, bone marrow, and semen) produced through a cycle of successive internal cooking and transformations. After ultimate distilling, the most concentrated and hence the most precious elixir among the constituents of the body is semen (*dhatu*). In *Charak Samhita*, disorders of *dhatus* have been elaborated and a syndrome resembling modern day Dhat syndrome by the name of *sukrameha* (*shukra* = sperm + *meha* = passage in urine) finds a prominent place. In *Susruta Samhita* and Ayurveda, loss of semen in any form leads to a draining of physical and mental energy and vitality.<sup>1,6</sup> This is further reinforced by the belief enshrined in religious scriptures according to which 40 meals produce one drop of blood, 40 drops of blood make one drop of bone marrow, and

40 drops of bone marrow form one drop of semen.<sup>7</sup> Considered in this religio-cultural perspective that is deeply ingrained in the minds of common folk in India, psychogenesis of the Dhat syndrome is easy to comprehend.<sup>1</sup>

## Epidemiology

Dhat syndrome is quite common in the natives of the Indian subcontinent.<sup>8-13</sup> It has been reported among Buddhists in Sri Lanka<sup>14</sup> and Pakistani Muslim expatriate workers in the Gulf states.<sup>15</sup> It is also widespread in Nepal, Bangladesh, and Pakistan.<sup>8</sup> Immigrants from these countries seen in European and North American clinics<sup>3</sup> do present with this sex-related disorder. The Dhat syndrome has acquired further International recognition by being included in Annex 2 (culture-specific disorders) of the ICD-10 Diagnostic Criteria for Research.<sup>16</sup>

## Clinical Features

Dhat syndrome is usually said to consist of the loss of semen in young men during micturition or while straining to pass stools.<sup>5</sup> Associated symptoms include vague and multiple somatic and psychological complaints such as fatigue, listlessness, loss of appetite, lack of physical strength, poor concentration, and forgetfulness. There may be accompanying anxiety or depressive symptoms. These patients may also present with or without psychosexual dysfunction.<sup>6,12,17</sup> The patient ascribes his symptoms, including sexual dysfunction, to the passage of Dhat (semen or some whitish substance presumed to be semen by the individual) in the urine as a direct result of excessive indulgence in sexual activity or masturbation.<sup>1</sup> Sometimes the sufferer may complain that semen has become foul smelling and less viscous.<sup>4</sup> Apart from a whitish discharge with urine, there are no other urinary symptoms. Urine examination fails to reveal any discoloration, sperms, or any other abnormal constituents except for the occasional oxaluria or phosphaturia.<sup>6</sup> The patient presenting with Dhat syndrome is typically more likely to be recently married, of average or low socioeconomic status (perhaps a student, laborer, or farmer by occupation), comes from a rural

area, and belongs to a family with conservative attitude toward sex.<sup>3,6,18</sup> The most common psychiatric disorders seen in patients with Dhat syndrome include depression, followed by generalized anxiety disorder.<sup>12,19</sup> Presence of concomitant systemic illnesses (resulting in turbidity in urine, e.g., diabetes mellitus, in-born metabolic disorders, urinary tract infections [UTIs], etc.) sexually transmitted diseases (STDs), local genital abnormalities, or drug dependence must be ruled out before labeling Dhat syndrome.<sup>3</sup>

Some researchers<sup>5</sup> have distinguished Dhat syndrome into three subgroups:

- Dhat syndrome alone
- Dhat syndrome with anxiety and depressive symptoms
- Dhat syndrome with sexual dysfunction

It is important to mention that an interview schedule for assessment of Dhat syndrome (DSIS) has already been introduced by research workers<sup>20</sup> at Chandigarh in order to assess this syndrome in the Indian male population.

### Patient's Knowledge, Attitude, and Expectations

Regarding the composition of Dhat, a majority of patients believe that it is semen, followed by those who believe it to be pus, sugar, concentrated urine, infection, or not sure of its composition.<sup>3</sup> Masturbation and/or excessive indulgence in sexual activities, venereal diseases, UTIs, overeating, constipation or worm infestation, disturbed sleep, or genetic factors are believed to be the main etiological factors.<sup>3,18</sup> Majority of these patients get the information about Dhat syndrome from friends, colleagues, or relatives, whereas, some get information from posters, advertisements in mass media, magazines, or quacks. Therefore, these patients prefer to visit STD clinics, urologists, and physicians rather than approach psychiatrists.

### Research on Dhat Syndrome in India

Malhotra and Wig<sup>21</sup> carried out a study to investigate the cultural basis of the Dhat syndrome. They interviewed 107 respondents from the general public. A large segment of the general public from all socioeconomic classes believed that semen loss is harmful. Seminal fluid was considered an elixir of life both in the physical and in the mystical sense, whose preservation guaranteed health, longevity, and super-natural powers. This belief was more frequent in lower socioeconomic classes. The susceptible individual would react to the prevalent belief system and to the fears of semen loss. The symptoms usually disappeared if the misconceptions about semen loss were effectively dealt with. It was expected that with increasing literacy and progress in sex knowledge the syndrome would become less common. Nakra et al.<sup>17</sup> studied 150 male patients presenting with male potency disorders. Of these, 10% had Dhat syndrome alone and another 10.7% had Dhat syndrome along with premature ejaculation or impotency. Compared to patients with sexual dysfunction, patients with Dhat syndrome considered loss of semen as harmful. Behere and Nataraj<sup>18</sup> studied

50 patients with complaints of Dhat syndrome and described the phenomenology of Dhat syndrome. It was most commonly seen in subjects of younger age (16–25 years) and from lower socioeconomic strata. It was commonly associated with impotency, marked anxiety, general weakness, premature ejaculations, and hypochondriasis. Body weakness and hypochondriasis were the commonest complaints. Most of the subjects (88%) were sure that the whitish discharge in urine was semen and majority of them had masturbatory guilt. Singh,<sup>12</sup> in his sample of 50 patients presenting with male potency disorders, reported that 40% fulfilled diagnosis of Dhat syndrome alone and another 22% had Dhat syndrome with impotence. Most of the patients (80%) also had comorbid anxiety and depressive neurosis. Another interesting finding in the study was that about two-third of the subjects did not attend the clinic after initial visit. Authors hypothesized that dissatisfaction with the explanation of disease provided to them could account for such early drop-out from the clinic. In another study from New Delhi, Chadda and Ahuja<sup>6</sup> studied 52 patients presenting with complaint of passage of Dhat in urine. They reported that only 13.5% had diagnosis of pure Dhat syndrome. Most of them had associated psychiatric disorders (neurotic depression–40.4%, anxiety neurosis–36.5%, hypochondriacal neurosis–5.8%, and psychogenic impotence–1.9%). They also reported poor follow-up rates. In another study, Chadda<sup>6</sup> studied illness behavior of 50 Dhat syndrome patients using a Hindi version of Illness Behavior Questionnaire and compared it with that of 50 controls. Two-third of Dhat syndrome patients received unspecified diagnoses on DSM-III-R. Patients with Dhat syndrome showed a distinct illness behavior profile consisting of higher scores on Illness Behavior Questionnaire factors of general hypochondriasis and affective discomfort and lower scores on denial compared with controls, suggesting that the disorder may be a distinct entity. Bhatia and Malik<sup>3</sup> examined 48 consecutive male patients of potency disorders, and reported that about two-third could be classified as Dhat syndrome with or without impotency and/or premature ejaculation; and only 20.8% had impotence alone and 14.6% had premature ejaculation only. The age range of Dhat syndrome patients was found to be 20–38 years (mean 23.5 years) while age of onset was 16–24 years (mean 20.6 years), majority of cases were unmarried (54.2%) and primary educated (79.1%). The cases with Dhat syndrome scored maximally on neuroticism and depression scales. Neurotic depression was the commonest associated psychiatric illness (39.5%), followed by anxiety neurosis (20.8%). The common presenting symptoms of Dhat syndrome included weakness (70.8%), fatigue (68.7%), palpitations (68.7%), and sleeplessness (62.4%), etc. Among the four groups, categorized on the basis of type of treatment (antianxiety drug, antidepressant, placebo, psychotherapy), the best response was seen in those receiving antianxiety or antidepressant drugs while those receiving psychotherapy showed minimal response. The overall dropout rate from treatment was 14.6% and the maximum dropout (40.6%) was seen in psychotherapy group. Bhatia and Malik<sup>3</sup> also reported that 93 of 144 patients with sexual problems complained of Dhat as a major concern. Forty-two percent of cases had diagnosis of Dhat

syndrome only and 23% had Dhat syndrome in combination with sexual dysfunction. In another study, Bhatia<sup>22</sup> studied 60 patients presenting with culture-bound syndromes and reported that Dhat syndrome was the most common culture bound syndrome (76.7%) followed by possession syndrome (13.3%). Depression was the most common associated psychiatric disorder in subjects with Dhat syndrome.

Dhat syndrome has also been described in females. Singh et al.<sup>23</sup> reported a 23-year-old female who attributed her multiple somatic complaints to wetness per vaginum experienced during sexual intercourse. In a study from National Institute of Mental Health and Neuro Science, Bangalore, authors evaluated 31 women who reported “passage of vaginal discharge” and studied the nature and frequency of symptoms considered to have been “caused” by the same. About one-third of the patients who reported passing (nonpathological) vaginal discharge harbored the mis-belief that passage of whitish discharge per vaginum was harmful to their health and that it was causing somatic symptoms in them. The authors considered this description to be akin to Dhat syndrome in men.<sup>24</sup>

## Research from Other Asian Countries

Besides being studied in India, Dhat syndrome has also been reported from and investigated in other South Asian countries. Mumford<sup>25</sup> studied men attending medical clinics in Lahore and reported that about 30% of the subjects complained of Dhat and the prevalence of Dhat was equal in patients with “functional” and “organic” diagnosis. Khan<sup>26</sup> studied the treatment seeking pattern of subjects with Dhat syndrome in Lahore and found that about 50% of the subjects sought help from Hakims; only 1.6% consulted a psychiatrist. In studies from Sri Lanka, De Silva and Dissanayake<sup>14</sup> and Dewaraja and Sasaki<sup>27</sup> studied men with sexual dysfunction and they reported that in many cases the subjects attributed their dysfunction to semen loss. Half of the patients also had somatic symptoms.

## Controversies about the Concept

Many controversies surround the concept of Dhat syndrome. Raguram et al.<sup>28</sup> argued that semen is one of the seven dhatus, hence use of term Dhat is over inclusive and it should be discarded. Authors from various parts of the world have disagreed with the concept of Dhat syndrome as a culture bound syndrome. Mumford<sup>25</sup> argued that “Dhat” should be primarily regarded as a culturally determined symptom associated with depression rather than a separate culture-bound syndrome. Other authors like Sumathipala et al.<sup>29</sup> and Jadhav<sup>30</sup> too reasoned that the symptoms of semen-loss anxiety are reported from various cultures and it should be considered as a culture related rather than culture-bound disorder.

## Management

The management of Dhat syndrome needs serious attention. This syndrome has become the domain of traditional therapeutic

resources, that is, quacks, Ayurvedic or Unani practitioners. The understanding of this condition by modern medicine fails to impress most patients and the explanation and reassurances offered prove not to be of much use. This is further amplified by a study from India, that compared psychological intervention with pharmacological management and not surprisingly found those receiving medications to benefit more at the end of 4 weeks of treatment.<sup>3</sup> Wig<sup>31</sup> too recommended empathic listening, a non-confrontational approach, reassurance, and correction of misbeliefs, along with the use of placebo, anti-anxiety and antidepressant drugs, whatever required.

Avasthi et al.<sup>32</sup> have developed a standardized treatment package for single males presenting with Dhat syndrome. It stresses on sex education and relaxation exercises. Sex education mainly focuses on anatomy and physiology of sexual organs and their functioning with reference to masturbation, semen formation, nocturnal emissions, and their functioning with genitourinary system independent of gastrointestinal tract. Relaxation therapy includes Jacobson's progressive muscular relaxation technique combined with biofeedback (as to facilitate objective evidence and mastering of anxiety by the patient) which should be practiced two to three times/day regularly especially after therapy sessions are over. If there is the presence of associated anxiety or depressive symptoms that may impede the process of therapy, anxiolytics, and/or antidepressants can be added for the least possible duration and in the least possible doses.

Indian Psychiatric Society has formulated clinical practice guidelines for management of various sexual disorders.<sup>33</sup> According to these guidelines, the first step in the management of Dhat syndrome involves evaluation for comorbid sexual dysfunctions, psychiatric disorders, and presence of possible UTI and STDs. Wherever there is a suspicion, local examination, appropriate investigations for infective pathology, and phosphaturia should be done and adequate treatment should be provided. Even after appropriate treatment of these ailments, if the symptoms persist then the subject should be provided with adequate sexual knowledge. Whenever patient has comorbid Dhat syndrome along with premature ejaculation or erectile dysfunction, Dhat syndrome should be treated first. If the psychiatric comorbidity is primary and/or severe, it should be addressed first. According to these guidelines also the most important aspect of treatment of Dhat syndrome is providing adequate sex knowledge and clarifying sexual myths.<sup>33</sup>

## Conclusion

There is sufficient clinical evidence regarding the existence of this culture-bound entity called Dhat syndrome. Due to the contribution of Wig and other researchers, this syndrome was included in the 10th edition of the International Classification of Diseases<sup>34</sup> under other specified neurotic disorders (F 48.8) with the provision of further research.

Apparently, this syndrome has a varied clinical picture. Some have the pure form of the disorder; others have concomitant diagnosable depression and anxiety disorder. Dhat syndrome

may also have comorbid psychosexual dysfunction ranging from concern about potency to frank impotence and premature ejaculation either alone or in combination. However, its phenomenology and prognosis needs to be studied further before this entity is accorded international acceptance.

## Introduction

Patients at increased risk for Sexually Transmitted Infections (STIs) are at increased risk for HIV and vice versa due to behavioral, social network, and biological factors.<sup>1-3</sup> Rates of STIs are highest among men who have sex with men (MSM), commercial sex workers, and adolescents.<sup>4</sup> Offering integrated sexual health services in clinics where these high-risk individuals seek care is an efficient strategy to screen, diagnose, treat, and prevent further transmission of STIs and HIV.<sup>5-7</sup> Clinical services for STIs and HIV include the following levels of intervention: prevention, screening, diagnostic testing, treatment, referral for treatment, and partner services. Ideally, to improve efficiency and optimize prevention opportunities in those at risk, these services will be integrated to the greatest extent possible. The range of services offered should be weighed based on the risks of the patient population served, the local epidemiology and the resources available. This chapter outlines the core elements of STI and HIV clinical services in both developed and resource-limited settings.

## Prevention

At a minimum, all patients should be screened with an STI/HIV risk assessment followed by tailored risk reduction counseling. Male and female condoms should be made accessible along with education on appropriate use. If available, pre-exposure vaccination to prevent hepatitis A and B and HPV should be offered to those at-risk who have not previously completed the vaccine series. In the US, Centers for Disease Control and Prevention (CDC) guidelines recommend hepatitis A vaccination for MSM and patients who use illicit drugs (both intravenous drug users [IDUs] and non-IDUs), and hepatitis B vaccination for all unvaccinated, uninfected individuals being evaluated for STIs. HPV vaccination for females age 9–26 years is also recommended.<sup>8</sup> Prevacination serologic screening for hepatitis A and B may save some costs but will also result in missed prevention opportunities due to delay of vaccination initiation in groups who may not return for test results.<sup>8</sup>

Pregnancy testing should be available as a point-of-service test wherever women of child-bearing age seek clinical services with referral to antenatal care or termination services when pregnancy is identified. For prevention of unintended pregnancy, women of child-bearing age attending STI and/or HIV clinics should be screened for pregnancy intentions, contraceptive use and counseled accordingly regarding effective pregnancy prevention. On-site availability of hormonal contraception should be provided if possible and if not, linkage to convenient contraceptive services should be in place. Best practices should include provision of emergency contraception when women who do not wish to become pregnant are evaluated within 5 days of unprotected intercourse.<sup>8</sup>

## Screening and Diagnosis of STIs and HIV

Screening guidelines have traditionally focused on gonorrhea, Chlamydia, syphilis, and HIV. Guidelines for screening of STIs vary by professional organization and take into consideration scientific evidence and expert opinion. Table 107.1 summarizes STI screening recommendations by risk group according to United Kingdom National Screening and Testing guidelines and United States Preventive Service Task Force (USPSTF) guidelines. Specific recommendations for screening and diagnostic tests available for STIs are presented in Chapter 109 and information on screening and treatment for viral hepatitis can be found in Chapter 32.

Table 107.2 shows a summary of UK and CDC guidelines on testing of trichomonas, syphilis and HSV. USPSTF does not provide recommendations on trichomonas testing but recommends serologic screening of syphilis only for patients at increased risk of syphilis infection and HIV screening only for patients at increased risk of HIV infection.<sup>10</sup>

In its recommendations, the USPSTF notes that being at “high risk” or “increased risk” for STIs can include risk irrespective of sexual behavior due to social network and socioeconomic factors that put patients at increased risk. For example, a patient who is in a monogamous relationship in a social network (such as

**Table 107.1:** Summary of United States Preventive Service Task Force and UK Guidelines on Testing of Gonorrhea and Chlamydia among Asymptomatic, Sexually Active Heterosexual Men and Women Attending STI, Adolescent or Family Planning Clinics and MSM based on Site of Possible Infection

a high school) with a high prevalence of Chlamydia might be at a higher risk of contracting Chlamydia than a patient with high-risk sexual behavior in a social network with a very low prevalence of Chlamydia.

For some STIs, local epidemiology, diagnostic test availability and available resources will influence whether testing and treatment of STIs is offered. In higher resource settings, we recommend at

a minimum offering the diagnostic testing and treatment for symptomatic individuals as described in the above tables. There is some variation for recommended screening of asymptomatic individuals in higher resource settings. Prioritization of screening for these infections in asymptomatic individuals should be based on morbidity associated with infection and prevalence in the communities served. In communities with low rates of return

for test results, point-of-service testing should be used if at all possible. Furthermore, although guidance on gonorrhea and Chlamydia screening may differ somewhat by different professional organizations, it is increasingly common for the testing platform in diagnostic laboratories to perform both tests simultaneously. Therefore, collective specimen testing for both gonorrhea and Chlamydia may be pragmatic, despite modest differences in the utility of screening among groups. Additional diagnostic testing may be indicated in patients with compatible clinical syndrome (i.e., lymphogranuloma venereum testing in MSM with symptoms of proctitis).

## FREQUENCY OF SCREENING

In many cases, there is limited data available to guide the interval for repeat screening. Screening for HIV and for other curable STIs at least once a year is recommended in MSM and sexually active adolescents.<sup>8</sup> More frequent screening (i.e., every 3–6 months) may be warranted in the setting of an epidemic or with very high risk sexual behavior such as multiple and/or anonymous sex partners, illicit drug use with sex, methamphetamine use, and/or sexual partners who engage in these activities.<sup>8</sup> In addition to receiving frequent diagnostic testing services, individuals practicing these behaviors should receive behavioral-based counseling and prevention services. Recommended frequency of asymptomatic screening among HIV-negative heterosexual adolescents and adults depends on the risk behavior of the individual and prevalence of the specific infection in the community.<sup>9</sup> Although annual screening for Chlamydia is a clear guideline for all sexually active young women, ideal frequency of screening in other groups is unknown.<sup>10</sup>

High rates of STIs have been reported among HIV-positive patients<sup>9,11</sup> and there is a well-documented increased risk of HIV transmission with STI coinfection.<sup>1–3,11</sup> Screening for STIs in HIV-positive patients at the time of initial HIV diagnosis should be standard, along with continued testing in continuity care depending upon behavioral risk factors. Annual syphilis serologic testing is recommended in HIV care.<sup>12</sup>

## SCREENING AND DIAGNOSIS OF STIs AND HIV IN PREGNANCY

Untreated STIs can have devastating consequences on pregnancy outcome. Maternal screening for HIV and syphilis as early as possible in the pregnancy allows for opportunities to intervene and prevent transmission to the fetus or infant. The following are summary recommendations for screening of pregnant women for STIs and HIV from the 2010 CDC STD Treatment Guidelines.<sup>8</sup>

### 1. HIV:

- (a) Test as early as possible in pregnancy for HIV.
- (b) Retest women at high risk for HIV in the third trimester (high-risk behavior identified during pregnancy, or linked to sexual networks at risk for HIV).

- (c) Refer all HIV-infected women for highly active antiretroviral therapy in a timely manner.
- (d) Conduct rapid HIV testing in women presenting in labor with undocumented HIV status. If the rapid test is positive, start antiretroviral prophylaxis to women in labor prior to receipt of confirmatory test result to prevent mother-to-child transmission.

### 2. Syphilis:

- (a) Conduct serologic testing for syphilis in the first trimester and/or when pregnancy is confirmed.
- (b) Rescreen women at high risk for syphilis again early in the third trimester and at delivery.
- (c) Screen infants of women whose syphilis status is unknown before discharge to home.
- (d) Screen any woman who delivers a stillborn infant for syphilis.

### 3. Hepatitis B:

- (a) Screen all pregnant women for hepatitis B with hepatitis B surface antigen (HBsAg) in the first trimester even if they have previously been vaccinated or tested.
- (b) Screen/rescreen all women who have not been previously tested for hepatitis B, are at high risk for hepatitis B and/or have clinical hepatitis at the time of admission for delivery.
- (c) Vaccinate all pregnant women at risk for hepatitis B and screen for hepatitis B prior to vaccination.
- (d) Expedited immunoprophylaxis should be given to infants of mothers who test positive for hepatitis B at the time of delivery.

### 4. Chlamydia:

- (a) Test all pregnant women at the first prenatal visit.
- (b) Retest women younger than 25 years and/or at increased risk for acquiring Chlamydia during the third trimester.
- (c) Women diagnosed with Chlamydia in the first trimester should be retested 3–6 months after diagnosis, preferably in the third trimester.

### 5. Gonorrhea:

- (a) Screen all pregnant women at risk for gonorrhea or living in areas with high prevalence of gonorrhea
- (b) Retest women at continued risk in the third trimester.
- (c) Women diagnosed with gonorrhea in the first trimester should be retested 3–6 months after diagnosis, preferably in the third trimester.

### 6. Hepatitis C:

- (a) Screen all women at high risk.

### 7. Bacterial vaginosis:

- (a) Evidence does not support routine screening of asymptomatic pregnant women for bacterial vaginosis (BV).

- (b) All symptomatic pregnant women with BV should be evaluated and treated.

#### 8. Cervical cancer screening

- (a) Screen all women with a Pap test as part of routine prenatal care.

#### 9. *Trichomonas vaginalis*:

- (a) Evidence does not support routine screening of asymptomatic pregnant women for *Trichomonas vaginalis*.
- (b) Symptomatic women should be evaluated and treated appropriately.

#### 10. HSV-2:

- (a) Evidence does not support routine screening for HSV-2 serology in previously undiagnosed pregnant women.

### Treatment/Referral for Treatment

If screening and/or diagnostic testing are offered for STIs, treatment should be made available to the patient by the clinic that provided the test. Whenever possible, point-of-services tests with high sensitivity and specificity should be utilized to decrease time to diagnosis and same-day treatment should be provided as indicated. Presumptive therapy prior to receipt of confirmatory diagnostic test result should be considered depending on the sensitivity of the diagnostic test, likelihood of suspected infection based on clinical presentation and local epidemiology, likelihood that the patient will return to receive test results and potential morbidity related to untreated infection.

For clinics that do not have expertise in HIV treatment services, patients diagnosed with HIV should be given timely referral to clinics that provide HIV treatment. A follow-up mechanism should be in place to ensure linkage to HIV care.

### HIV CLINICAL SERVICES

Core components of HIV clinical services include clinical evaluation and staging of HIV infection by a clinician trained in HIV care, routine laboratory evaluation with CD4 and HIV viral load, prescription of antiretroviral therapy and opportunistic infection prophylaxis when indicated, treatment-adherence counseling, and risk-reduction counseling. Risk-reduction counseling includes pre-conception counseling, discussion of risky sexual and drug use behaviors as well as counseling of HIV discordant couples (preferably together). STI and family-planning services should also be included in HIV clinical care both for the health of the HIV-positive patients receiving services and to decrease transmission to others. See Chapter 115 for guidelines on treatment of HIV in industrialized and resource-limited settings.

### Screening and Treatment of STIs in Resource-Limited Settings

Efficient allocation of resources to address STIs and HIV is a priority in all clinical venues but is of particular concern in resource-limited settings. The greatest share of the global burden of STIs and HIV occur in these countries where availability of treatment is often limited and diagnostic testing is often unavailable and/or unreliable.<sup>13</sup> To efficiently diagnose, treat and decrease transmission of STIs in asymptomatic individuals, the WHO recommends syndromic management with targeted diagnostic screening to high-risk individuals, integration of STI and HIV screening in family planning clinics, and enhanced partner services including expedited partner therapy.<sup>7</sup> In syndromic management, STI-associated syndromes are recognized and empirically treated with medications that target the most common causes of the specific syndromes without the use of diagnostic tests.<sup>7,14</sup> Algorithms for management are developed based on the local prevalence and the antimicrobial susceptibility of the most likely etiologies of the syndromes. Syndromic case management has generally been shown to be cost-effective in many low-resource settings, particularly when applied to clinical scenarios in males and with genital ulcer syndromes. Reports indicate that the syndromic approach to cervicitis in women has less utility, and refining approaches here may be an area for productive clinical research.<sup>14</sup> For more information on syndromic management of STIs, see also Chapters 56, 60, and 61.

### Partner Services

In order to break the chain of STI transmission to the wider community, sexual partners of patients with STIs must be treated. Ideally, partner-management services can be integrated into the clinic in which the index receives care. Through partner services, sexual contacts of patients diagnosed with STI(s) are informed of their exposure, offered evaluation and presumptive treatment for infection, and counseled on prevention of future infection.<sup>5</sup> Partners can be notified through the index patient and/or with the assistance of the local health department with level of partner notification services available varying by STI prevalence and resources available. Through partner notification and treatment, index patients are at decreased risk for reinfection and at a population level, rates of forward transmission are inferred to be decreased.<sup>8</sup>

In resource-limited settings and in situations where partners are unable or unwilling to come to clinics for evaluation and treatment, expedited partner therapy (EPT) may be considered. In this intervention, partners of infected patients are treated through medications or prescriptions without medical evaluation or prevention counseling. Compared to standard partner services, EPT has been shown to increase likelihood of partner treatment and decrease exposures to untreated partners compared to unassisted patient referral. EPT also leads to decreased risk of reinfection with gonorrhea or Chlamydia compared to standard partner services.<sup>15</sup> For more details on partner services and EPT see Chapter 17.

### Summary

Through integrated STI, HIV and family planning services, individuals with high-risk sexual behavior are targeted for screening, diagnosis, and treatment of STIs and unintended pregnancy. The services clinics provide will depend on the patient population served, burden of disease, local epidemiology, and resources available. Guidelines for screening and treatment are available and should be tailored to meet the needs of the communities served. With this approach, reduction of the significant individual and public health costs associated with STIs and HIV can be achieved.

# Medicolegal Aspects of Sexually Transmitted Infections and Sexual Assault

Margaret R. Hammerschlag

108

## Sexually Transmitted Infections and Sexual Assault in Children

Testing for sexually transmitted infections (STIs) in children presents a number of problems for the practitioner that are not usually faced when testing adults for the same infections. The identification of an STI in a child can have serious legal in addition to medical implications. The presence of an STI is often used to support the presence or allegations of sexual abuse and conversely, the identification of an STI in a child will prompt an investigation of possible abuse. Although the identification of sexually transmissible agents in children beyond the neonatal period suggests sexual abuse, exceptions do occur. Perinatally acquired rectal or vaginal *Chlamydia trachomatis* infection may persist for 2–3 years after birth.<sup>1</sup> Genital warts have been diagnosed in children who have been sexually abused, but also in children who have no other evidence of sexual abuse.<sup>2–5</sup> Bacterial vaginosis (BV) has been diagnosed in children who have been abused, but its presence alone does not prove sexual abuse.<sup>6</sup> However, postnatally acquired gonorrhea; syphilis; and nontransfusion, nonperinatally acquired HIV are virtually diagnostic of sexual abuse.<sup>7</sup>

## Epidemiology of STIs in Children being Evaluated for Suspected Sexual Abuse

Studies of STIs in children have demonstrated significant variability in the prevalence of infection. In many of the earlier studies, only symptomatic children were tested, which often gave higher prevalence of gonococcal infection than studies that tested all children being evaluated for suspected sexual abuse. However, the prevalence of STIs in sexually abused children is low, usually 3% or less.<sup>8–12</sup> The results of four recent studies examining the epidemiology of STIs in children and adolescents being evaluated for suspected sexual abuse are summarized in Table 108.1. Three studies were retrospective chart reviews, including one each from Vienna, Austria<sup>8</sup>; Auckland, New Zealand<sup>9</sup>; and Miami, Florida.<sup>10</sup> Charts were examined from a total of 4350 children, who were seen over periods ranging from 4 to 7 years. The ages ranged from 0 to 17 years and the overwhelming majority was female. Despite differences in population and methodologies, the results of these studies were fairly consistent. The prevalence of STIs, specifically gonorrhea and *C. trachomatis*, was low, ranging from 0.4% to 1.8%. No child was found to have syphilis or

#Testing only done in children with lesions suggestive of HSV.

HIV by serology. As these were retrospective chart reviews they had a number of major limitations. There were different inclusion criteria and not every child or adolescent was tested for every STI. Giradet et al.<sup>12</sup> prospectively examined children 0–13 years of age being evaluated for suspected sexual abuse/assault at 7 tertiary care centers in the United States (Houston, TX; Atlanta, GA; Harrisburg, PA; and New York City, NY). All children were tested at multiple sites for *N. gonorrhoeae* and *C. trachomatis* by culture and vaginal and urethral swabs and urine were also tested using two nucleic acid amplification tests (NAATs). Wet mounts were performed for *T. vaginalis* and cultures for herpes simplex virus (HSV) were done if lesions were present. Sera were also obtained for testing for syphilis, HIV, and type specific antibody for HSV-1 and 2. A total of 536 children were enrolled, 485 (90.5%) were female. None of the 51 boys enrolled were positive for any STI. Overall, 40 (8.2%) of the girls were found to have one or more STIs. *C. trachomatis* and *N. gonorrhoeae* were detected by culture and/or NAAT in 15 (3.1%) and 16 (3.3%) of the girls enrolled, respectively. *T. vaginalis* was detected by wet mount in 5 of 85 (5.9%) symptomatic girls tested. Serologic evidence of syphilis was found in only one of 384 (0.3%) children. This child also was positive for *N. gonorrhoeae*. None of the children were positive for HIV. Cultures for HSV were obtained from only 12 children who had lesions suggestive for HSV, 5 (41.7%) were positive, but only 1 of the culture positive children had type specific HSV-2 antibody. Although girls who presented with vaginal discharge were more likely to have a positive test result (24.5% vs 6.3%), 67.5% of the children with a confirmed STI had normal or nonspecific anogenital findings. The overall prevalence of STIs varied from site to site, ranging from 1.7% in Texas to 7.8% in Atlanta.

## Diagnosis of STIs in Children

As the prevalence of STIs in children is low, the positive predictive value of a test is more important than in an adult victim of assault. One needs to use tests with the highest specificity. One cannot extrapolate the performance of a test in adults to children.

### NEISSERIA GONORRHOEAE

The identification of *N. gonorrhoeae* in a child beyond the neonatal period is indicative of some kind of sexual contact. The Centers for Disease Control and Prevention (CDC) 2006 STD Treatment Guidelines recommends that specimens for culture of *N. gonorrhoeae* be collected from the pharynx and anus of girls and boys, the vagina in girls, and the urethra in boys being evaluated for suspected sexual abuse.<sup>7</sup> The Guidelines also specifically stated that Gram-stained smears not be used for the diagnosis of gonorrhea in children. The 2010 Guidelines now include recommendations for the use of NAATs for detection of *N. gonorrhoeae* in children.<sup>13</sup> Use of NAATs has supplanted standard culture methods for *N. gonorrhoeae* in many laboratories. All the currently available assays have approval from the US Food

and Drug Administration (FDA) for use in genital sites (cervix, vagina, urethra) and urine from adolescents and adults. None are approved for extragenital sites in adults (pharynx or rectum) or for any site in children.

To date, there have been three published studies that compared NAATs to *N. gonorrhoeae* culture in children being evaluated for suspected sexual abuse.<sup>14–16</sup> All included urine specimens as well as vaginal swabs. Although the results of the two earlier studies suggested that the sensitivity of NAATs for *N. gonorrhoeae* was similar to culture, they both had several serious limitations: the populations studied were predominantly female and included adolescents up to 18 and 20 years of age many of whom reported consensual sexual activity, only 23.7% and 41.5% of the children enrolled were prepubertal<sup>14,15</sup> and both studies utilized ligase chain reaction (LCR, LCx, Abbot Diagnostics), which was taken off the market in 2002 because specificity concerns for detection of *N. gonorrhoeae*.<sup>17</sup> Other study limitations included the failure to use an independent reference standard in estimating test performance, failure to separately analyze test performance by age and gender (when applicable). The prevalence of *N. gonorrhoeae* infection in both studies was low (1.9% and 3.2%) reducing the precision of sensitivity estimates. The number of extragenital specimens was also too low to assess test performance at those sites. Black et al. recently evaluated the use of strand displacement amplification (SDA) and transcription mediated amplification (TMA) vs. culture for diagnosis of *N. gonorrhoeae* in children, 0–13 years of age, evaluated for sexual abuse in four US cities.<sup>16</sup> All children were tested at multiple sites for *N. gonorrhoeae* and *C. trachomatis* by culture and vaginal and urethral swabs were tested with SDA and urine with SDA and TMA. Positive NAATs for *N. gonorrhoeae* were confirmed by an in-house PCR using an alternate target, the *Hinf*I fragment of the 4.2-Kb cryptic plasmid.<sup>18</sup> A total of 536 children were enrolled, none of the 51 boys were positive for *N. gonorrhoeae* by any test at any site. Of the 485 female participants, 16 (3.3%) had a positive result for *N. gonorrhoeae* by any test: 12 (2.5%) by culture, 14 (2.9%) by vaginal NAAT, and 14 (2.9%) by urine NAAT. All participants who had a positive vaginal culture for *N. gonorrhoeae* had positive urine NAATs. There were discrepant results in two cases (both SDA-positive and TMA-negative). One of these girls was positive in urine and negative by vaginal swab, the other was positive both by urine and swab. All SDA-positive results for *N. gonorrhoeae* were confirmed to be true positives by a species-specific *N. gonorrhoeae* PCR. Three girls had discrepant results by site: two were vaginal swab positive and urine negative, one was vaginal swab negative and urine positive. The results of this study suggest that SDA and TMA may be alternatives to culture for the detection of *N. gonorrhoeae* in vaginal swabs and urine in prepubertal girls.

Not all NAATs perform equivalently. PCR and SDA have both been demonstrated to have cross reactivity with other *Neisseria* species including *N. cinerea*, *N. flavescens*, *N. lactamica*, *N. sicca*, and *N. subflava*.<sup>19–21</sup> This can have important implications especially when testing extragenital sites, especially the pharynx.

Although false-positive results were not observed with SDA in the multicenter study,<sup>16</sup> it still remains a possibility, especially if the assay is used more widely. Additional testing is still essential as the prevalence of gonorrhea in children being evaluated for suspected sexual abuse is low; low positive predictive values have been reported in low-prevalence adult populations.<sup>22</sup> One cannot extrapolate from these results to other NAATs, specifically PCR, or use in extragenital specimens (pharynx, rectum) or in any site in boys.

## CHLAMYDIA TRACHOMATIS

The prevalence of *C. trachomatis* infection in abused children is also low (Table 108.2). Genital infection with *C. trachomatis* in children is frequently asymptomatic and may persist for months to years.<sup>23</sup> The 2006 CDC Guidelines recommended that children being evaluated for suspected sexual abuse be tested for *C. trachomatis* at the anus in both boys and girls and from the vagina in girls.<sup>7</sup> Culture was the preferred test. Pharyngeal specimens from children of either sex are also not recommended, as the prevalence of *C. trachomatis* infection at this site is very low in children being evaluated for suspected sexual abuse. The isolation of *C. trachomatis* in tissue culture should be confirmed by the microscopic identification of the characteristic intracytoplasmic inclusions, preferably with a species-specific fluorescein-conjugated monoclonal antibody.<sup>7</sup> Use of genus-specific antibody for culture confirmation can lead to misidentification of *C. pneumoniae* as *C. trachomatis* in pharyngeal specimens.<sup>24</sup> Enzyme immunoassays (EIAs) are not acceptable as confirmatory tests and have been associated with false positive results, especially when used with vaginal and rectal specimens.<sup>25–28</sup>

NAATs are currently approved by the FDA for detection of *C. trachomatis* from genital sites (cervix, vagina, urethra) and urine from adolescents and adults. None are approved for extragenital sites (pharynx or rectum) in adults or have approval for any site in children. These methods have been found to have excellent sensitivity for detection of *C. trachomatis*, usually well above 90%, in genital specimens and urine from adult men and women, while maintaining high specificity.<sup>29</sup> The 2006 STD Treatment Guidelines recommended that NAATs can be used in children being evaluated for suspected sexual abuse if culture is not available and if positive results can be confirmed.<sup>30</sup> Confirmation was specified as use of another NAAT that utilized a different genetic target, however, not all NAATs perform equally.<sup>29</sup> Use in extragenital specimens was not discussed. As with *N. gonorrhoeae*, data on the use of available NAATs for detection of *C. trachomatis* in children are limited. The number of studies is small and have the same limitations described previously for evaluation of NAATs for *N. gonorrhoeae*.<sup>14,15,30</sup> The recent multicenter study by Black et al.,<sup>16</sup> also evaluated the use of SDA and TMA with urine and genital swabs (vagina and urethra) compared to culture for diagnosis of *C. trachomatis* in children. All samples were processed and tested according to manufacturers' protocols except for the TMA tests which were performed on previously frozen urine or swabs collected in the BD ProbeTec sample collection medium. Test results that were positive by SDA for *C. trachomatis* were confirmed using an in-house PCR targeting the *ompA* gene, performed at the CDC.<sup>31</sup> Fifteen (3.1%) of 485 female participants had a positive result for *C. trachomatis* by any test (1.4% by culture; 2.3% by vaginal NAAT; 2.7% by urine NAAT). None of the male participants had any positive

**Table 108.2:** Recommended Tests for STIs in Children Being Evaluated for Suspected Sexual Abuse

Infection	Reportable as sexual abuse	Sites and specimens	Recommended tests
<i>N. gonorrhoeae</i>	Diagnostic	Vagina, urethra (males), rectum, pharynx, urine (if NAAT is used)	Culture on selective media, isolates confirmed by at least 2 methods that use different principles. NAATs <sup>†</sup> in vaginal swab or urine from girls. NAATs not approved for pharynx or rectum
<i>C. trachomatis</i>	Diagnostic <sup>*</sup>	Vagina, urethra (males), rectum, urine (if NAAT is used)	Culture: tissue culture, confirmation by staining with FA conjugated species-specific monoclonal antibody with visualization of characteristic intracytoplasmic inclusions. NAATs <sup>†</sup> may be used if culture is not available and results can be confirmed by a second NAAT. NAATs not approved for rectal specimens.
Syphilis	Diagnostic <sup>*</sup>	Serum, active lesions	Serology: initial screening with nontreponemal test, confirmation with treponemal test. Darkfield microscopy to identify treponemes in lesions
HSV	Suspicious	Lesions on vagina, urethra (males), rectum	Culture. Screening using type-specific serology not recommended
<i>T. vaginalis</i>	Highly suspicious	Vagina	Examination of vaginal wet mount. Culture
HPV	Suspicious	Vagina, urethra (males), rectum	Physical examination. Biopsy and HPV typing of lesions
HIV	Diagnostic <sup>*</sup>	Serum	EIA, followed by WB, viral load

\* If perinatal acquisition can be ruled out.

<sup>†</sup> Data on use of NAATs in children limited to SDA and TMA, vagina and urine in females.

cultures or NAATs for *C. trachomatis*. All participants who had a positive vaginal culture for *C. trachomatis* also had positive urine NAAT. Two girls had positive *C. trachomatis* cultures from rectal swab specimens, but negative vaginal swab specimens by both culture and NAATs, and negative urine NAATs. There were no discrepant results in any of the participants tested by SDA and TMA for *C. trachomatis*. All *C. trachomatis*-positive results were confirmed by DNA sequence genotyping. The sensitivity of vaginal culture for *C. trachomatis* was 39% in all girls studied. In contrast, the sensitivities of urine and vaginal swab NAATs were 100% and 85% in all female children, respectively, for detection of *C. trachomatis*. The results of Black et al.<sup>9</sup> suggest that NAATs can be used for detection of *C. trachomatis* in girls being evaluated for suspected sexual abuse. However, the same limitations apply as for use of these assays for detection of *N. gonorrhoeae*: (i) As the prevalence of *C. trachomatis* in this population is low, additional testing is probably necessary. (ii) One cannot extrapolate from these results to other NAATs, specifically PCR and use in specimens other than vagina and urine in girls. (iii) One cannot make any recommendations on the use of these assays in prepubertal boys. Some of the more recently available commercial NAATs, such as TMA (Aptima 2), offer an alternate target confirmation method that can be used on the same testing platform; however, there are no data on the use of this confirmatory test in this setting. Additional options include sending blinded specimens to an independent or reference laboratory for confirmation testing, confirming a NAAT-positive result by culture test (requires a separate, invasive specimen), or use of a second, alternate technology commercial NAAT. Specimens collected from children for forensic applications should be retained in the laboratory for purposes of additional testing, in accordance with local policies and procedures.

## SYPHILIS

The prevalence of syphilis in these children has been <1% in most studies.<sup>8–12</sup> Diagnosis of syphilis was based on serologic screening as most of these children were asymptomatic. Cases of symptomatic syphilis appear to be uncommon and are mostly limited to anecdotal reports. Clinical findings have included primary chancres, manifestations of secondary syphilis including rash and condyloma lata, which can be misdiagnosed as genital warts.<sup>32</sup> The major confounding variable in the diagnosis of syphilis in children beyond the neonatal period is differentiating between acquired and congenital infection. As most pregnant women in the US are screened for syphilis during pregnancy, congenital infection could be ruled out if maternal records can be accessed. However, this may not always be possible and some of the clinical manifestations of congenital syphilis may overlap with those of acquired syphilis.

## HERPES SIMPLEX VIRUS

The presence of genital herpes in a prepubertal child also raises the probability of sexual abuse. However, available data are too limited

to allow estimation of the likelihood of sexual transmission. The overwhelming majority of published studies of STIs in children being evaluated for sexual abuse have limited studies for HSV to children who presented with suggestive genital lesions. The prevalence of HSV infection in these studies was low, <5%.<sup>8–12</sup> In the multicenter study reported by Giradet et al., only 12 girls were found to have genital ulcers, and only five were culture positive for HSV.<sup>12</sup> As most studies have only tested symptomatic children, we have no way of knowing how common asymptomatic infection may be in these children, even as more evidence emerges about the frequency of asymptomatic and subclinical infections in adults.

Data on use of type specific serology for HSV-1 and 2 in children are very limited. Ramos et al., compared HerpeSelect HSV-2, Biokit HSV-2 Rapid Test (Biokit), and western blot (WB) in sera from 150 children being seen in a sexual abuse clinic.<sup>33</sup> The ages ranged from 1 to 18 years and 81% were female. Fifty-one percent of the children were HSV-1 seropositive by WB. In contrast, <1% were seropositive for HSV-2. Although 8 patients were positive for HSV-2 by at least one test, only one individual was positive by all three tests, an adolescent girl who reported consensual sexual activity. Six children were positive by HerpeSelect HSV-2, but negative by Biokit and WB and 137 samples were consistently negative. None of the children had clinical genital herpes. Sera from 283 children enrolled by Giradet et al.<sup>12</sup> were tested for HSV-1 and 2 antibodies using an immunodot enzyme assay with a monoclonal antibody inhibition for confirmation performed at the CDC. Antibody to HSV-1 and HSV-2 was detected in 45.6% and 2.5% of the children, respectively. Three children had antibody to both HSV-1 and 2. As stated previously, cultures for HSV were obtained from only 12 children who had lesions suggestive of herpes, but only one of five culture positive children had HSV-2 antibody. These data suggest that type-specific serology for HSV has a poor predictive value for diagnosis of HSV infection in children being evaluated for suspected child abuse, based on a single serum sample. Furthermore, as demonstrated by Ramos et al.,<sup>33</sup> the performance of even FDA approved tests can be inconsistent in a low prevalence population.

## TRICHOMONAS VAGINALIS

Although *T. vaginalis* is probably the most prevalent nonviral STI among adults in the US, data on this infection in the setting of child sexual abuse are limited. Most published studies of STIs in sexually abused children have testing for *T. vaginalis* was limited to girls presenting with vaginal discharge.<sup>8–12</sup> Rarely *T. vaginalis* can be transmitted vertically from mother to infant (vaginal, urine) during parturition.<sup>34</sup> These infections may persist for several months after birth. Care should be taken in interpretation when trichomonads are reported present in urine specimens from children collected for another purpose. As the morphology of *Pentatrichomonas (Trichomonas) hominis*, a nonpathogenic intestinal flagellate, is very similar to that of *T. vaginalis*; care must be taken to make sure that specimens are not contaminated with fecal material which can occur with bagged urine specimens.

Culture for *T. vaginalis* on Diamond's medium has a high sensitivity (95%) and specificity (>95%) in adult women.<sup>35</sup> Incubation periods of 2–7 days are needed to identify *T. vaginalis* in culture.<sup>35</sup> There are several point of care tests available including the Affirm VP III Microbial Identification System (Becton Dickinson) test, which is a direct nucleic acid probe hybridization test for detection of *T. vaginalis*, *Gardnerella vaginalis*, and *Candida spp.*<sup>36,37</sup> It has been reported to have sensitivities of 80–90% in adult women with vaginitis.<sup>36</sup> The Affirm VP III has not been validated or approved for use in genital specimens from prepubertal girls or urethral specimens from men.

## HUMAN PAPILLOMAVIRUS (HPV)

The association of genital warts and sexual abuse in children is complicated by the long period of latency before lesions become clinically apparent and possibility of nonsexual transmission, either vertically during delivery or horizontally after birth. The criteria for diagnosis of HPV infection in children, clinical versus detection of HPV DNA, are also not standardized. Most published studies of HPV infection in children being evaluated for sexual abuse have relied on the presence of clinical lesions consistent with genital warts for the diagnosis of HPV infection.<sup>2,8–12</sup> Given the possible role of perinatal transmission for anogenital and respiratory HPV (laryngeal papillomatosis) infection, an important issue has been at what age is the presence of HPV infection due to sexual abuse. Although studies and reviews of the subject have suggested that 24 months of age was the upper limit for anogenital warts in children to be secondary to perinatal transmission, a significantly longer incubation period,  $\geq 5$  years, has been suggested for laryngeal papillomatosis.<sup>4</sup>

The diagnosis of HPV infection in children has been primarily clinical. Lesions suspicious for HPV should be biopsied and tested for HPV. Several studies have evaluated detection of HPV DNA in children being evaluated for suspected sexual abuse, however the results have been contradictory.<sup>2–5,38</sup> Studies published since 2000 have demonstrated poor correlation of detection of HPV DNA by PCR and presence of genital warts.<sup>3–5</sup> There is also a great deal of heterogeneity of the PCR methods used. Due to the large number of HPV types involved in genital disease, type-specific PCR assays are not practical for detection of HPV. Most have used generic primers followed by either probing or sequencing of the products. Nested-PCR assays were used in some studies. Use of generic HPV PCRs may be less sensitive than specific HPV 16 PCR. Even so, the association of the presence of HPV DNA with abuse is not very strong. HPV DNA has been detected in genital and rectal swabs in 15% of girls thought to be abused, and it has also been detected in vaginal and/or anal specimens from 2.1% of healthy children with no history of abuse.<sup>3–5,38,39</sup>

# Sexually Transmitted Infections: Screening and Diagnostic Practices

Charlotte A. Gaydos

# 109

## Introduction

Sexually transmitted infections (STIs) are of utmost importance because of their cosequential diseases/complications. These are especially concerning in women, who can experience cervicitis, endometritis, pelvic inflammatory disease (PID), chronic pelvic pain, adverse birth outcomes, and infertility. In men, gonorrhea and chlamydia infections cause urethritis, epididymitis, and proctitis. Ulcerative diseases such as syphilis, lymphogranuloma venereum (LGV), chancroid, and herpes simplex virus (HSV) can cause systemic illness. Long-term adverse health events include the sequelae of untreated STIs, such as chronic pelvic pain, tubal infertility, vertical transmission to neonates, and for both men and women increased risk of HIV transmission and acquisition.<sup>1</sup>

Sexually transmitted infections disproportionately impact individuals with various demographic and behavioral risk factors, or persons who live in defined geographic areas. The prevalence of STIs is higher among young adults aged 15–24 years, urban dwellers, and individuals with high-risk sexual behavior, such as multiple partners or exchanging sex for money or drugs.<sup>2</sup>

## Rationale for Screening Practices

Many if not most STIs are asymptomatic; thus, screening of individuals is highly recommended. Screening can be defined as performing tests for STIs among individuals who do not have symptoms of an STI and who are not presenting to a clinician because of symptoms or being a named contact of a person who is infected, where “diagnostic” testing may be performed. The World Health Organization (WHO) recommends assessment and testing for syphilis, gonorrhea, chlamydia, trichomoniasis, genital ulcer disease, and urethral discharge in settings where patients are seen, and also in settings without relation to symptoms, including detention facilities, military recruitment, routine sex worker examinations, and women at delivery.<sup>2</sup> The primary goals of STI assessment and monitoring are to identify population subgroups with a high prevalence of disease, to monitor trends in STI prevalence, and to prevent transmission and morbidity due to asymptomatic infection.<sup>2</sup> Limited financial

and personnel resources have led to the development of selective screening criteria in some areas in order to maximize identification of infected persons when resources are limited which limit the number of persons screened.

Asymptomatic infection or mild symptoms can lead to delay in diagnosis and treatment.<sup>3</sup> Syndromic diagnosis will not work to detect individuals with asymptomatic or unrecognized infection; such persons are an important reservoir for continued transmission to partners. Thus, the importance of regular screening among high risk populations must be adopted rather than syndromic treatment, which has been the WHO standard of care. The syndromic management approach has low sensitivity and low positive predictive value.<sup>2</sup> Selective screening is often instituted because of resource constraints, but requires a local prevalence study first to identify those at risk in a particular population. Numerous studies have shown that screening for STIs, based on age, behavioral, and clinical characteristics, or in some instances universally, effectively prevents the costly consequences of disease progression.<sup>4–7</sup> Selective screening algorithms, based on demographic and behavioral risks, have been explored in a variety of situations in an attempt to maintain efficient use of resources. This chapter discusses STI screening strategies and new sample types that are aimed at maximally preventing morbidity and transmission. Age has been determined to be an excellent predictor of risk for chlamydia infections. Both <25 and <30 have been found to be useful in large screening programs.<sup>4,8,9</sup> Studies have also shown that individuals who practice high risk sexual behaviors, such as new or multiple sex partners or who do not use condoms, are at greater risk for chlamydia infections.<sup>8,10</sup>

## Screening for Sexually Transmitted Infections to Prevent Morbidity and Sequelae

### CHLAMYDIA TRACHOMATIS AND NEISSERIA GONORRHOEA

Screening interventions for chlamydia and gonorrhea in women in developed countries are cost-effective because of the estimated savings in prevented future consequences of PID and infertility. It is estimated that 10–25% of women with untreated chlamydia

and gonorrhea will experience PID, 20% of women with PID will have tubal infertility, and 9% will have ectopic pregnancies.<sup>4,5,11</sup> A study of fertility among 1844 women with abnormal laparoscopy and suspected PID found 10.8% had a confirmed tubal factor infertility, and 9.1% ectopic pregnancy rate, compared to 0% and 1.4%, respectively, among 657 women with normal laparoscopic findings.<sup>12</sup> Ectopic pregnancy, tubal infertility, chronic pelvic pain, and other long-term consequences of PID, such as ectopic pregnancy, are estimated to occur among 15% to 20% of women with PID.<sup>12,13</sup>

A large proportion of chlamydia and gonorrhea infections, in both men and women are asymptomatic, with percentages ranging from 30% to 50% in men, and 60–80% in women.<sup>11,14</sup> In women especially, symptoms are variable and can be nonspecific, leading to delay in diagnosis and treatment seeking.<sup>3,12</sup> A randomized, controlled trial evaluating an enhanced screening intervention for chlamydia found a reduced incidence of PID among women who received screening compared to those who sought care based on symptoms.<sup>15</sup> Early detection and treatment with subsequent prevention of long-term health consequences and vertical transmission is facilitated by screening among asymptomatic individuals. However, screening in many settings is hampered by the relative lack of clinical facilities and by the cost of the tests themselves.

### Diagnostic Methods—Chlamydia

Historically, chlamydiae were cultivated in tissue culture, but cell culture has been replaced by nonculture assays. Culture for detection of chlamydiae in clinical specimens is generally now only performed at reference laboratories. The first nonculture assays, such as Direct Fluorescent Antibody (DFA) staining of direct patient material and enzyme immunoassay, have been replaced by molecular tests which can amplify the nucleic acids in clinical specimens are currently the tests of choice and several are available commercially.<sup>16–19</sup> These nucleic acid amplification tests (NAATs) are currently recommended by Centers for Disease Control and Prevention (CDC) as the diagnostic assay of choice.<sup>20</sup> Inexpensive, point-of-care tests (POC), which can be used by minimally trained healthcare workers, are desperately needed. Such tests could eliminate the need for clinical facilities and could be used in community settings.<sup>21</sup>

### Diagnostic Methods—Gonorrhea

The gram stain and culture on specialized laboratory media with biochemical confirmatory assays has been used for many years to detect *N. gonorrhoeae* in clinical specimens.<sup>22</sup> Urethral smears from males with symptomatic gonorrhea have a sensitivity of 90–95.0%.<sup>23</sup> Endocervical smears from females and rectal specimens require careful interpretation, because of colonization with other gram-negative coccobacillary organisms and in females the sensitivity of an endocervical Gram-stain is estimated to be 50–70.0%.<sup>23</sup> Presently, the nucleic acid-based tests (NAATs) are the most sensitive assays available and are currently recommended by the CDC.<sup>20</sup>

### Choice of Specimen Type for Screening

For chlamydia and gonorrhea, the samples traditionally used have been cervical swabs for females and urethral swabs for males. However, due to the extreme increase in sensitivity and specificity of NAAT assays, less invasive samples such as urine for both females and males, as well as vaginal swabs for females, can be also used. Centers for Disease Control (CDC) now recommends that for screening of asymptomatic women the self-collected vaginal swabs should be used, since they are slightly more sensitive than urine.<sup>20</sup> However, urine screening tests are often used in outreach screening programs.

When pelvic examinations are being performed for symptoms or because a Pap test is required, the cervical swab is usually preferred as this sample type has been shown to have a slightly higher organism load for chlamydia.<sup>24</sup> However, if an individual is not receiving a pelvic examination, clinicians should take advantage of the ease of obtaining a urine sample or a self-collected vaginal swab for amplification testing for chlamydia and gonorrhea. Vaginal swabs are therefore the preferred sample type for screening; as well, they are highly preferred by many women.<sup>25–33</sup> Such samples can eliminate the necessity for a clinician-performed pelvic examination for asymptomatic women for sample collection and may be cost savings, when a Pap test is not required.<sup>34</sup> For males, urine specimen is the sample of choice for the detection of chlamydia.<sup>35,36</sup> Infections detected by NAATs may be up to 80% higher than those found with the use of older technology.<sup>37</sup>

The resulting expansion of screening programs for chlamydia and gonorrhea has resulted in recommendations by professional organizations and public health officials in the United States to screen all sexually active women <26 years yearly or those >26 years with sexual risk factors.<sup>38,39</sup> No official recommendations exist for men but CDC guidance has been published.<sup>40</sup>

### Alternative Specimen Types

Rectal and pharyngeal specimens are important sample types for detection of chlamydia and gonorrhea in men who have sex with men (MSM). Such sample types are not cleared by the FDA, but have been extensively demonstrated by many research studies to perform well with NAATs assays and yield better results than culture.<sup>41,42</sup> However, specimens from rectal and pharyngeal sites require verification of test performance by individual laboratories before use. Eye samples from babies or ocular samples from adults can be tested by NAATs, but since FDA clearance has never been obtained for commercial tests, laboratories must perform their own verification studies. NAATs are also becoming increasingly used for diagnostic assays for cases of sexual abuse.<sup>43</sup>

### Diagnostic Considerations and Assay Choice

Because NAATs measure nucleic acids instead of live organisms, caution should be used in using NAATs for test-of-cure assays. Residual nucleic acid from cells rendered noninfective by antibiotics may still give a positive amplified test up till 3 weeks after

therapy, when the patient is actually cured of viable organisms.<sup>44,45</sup> Therefore, clinicians should not use NAATs for test-of-cure until after 3 weeks. The CDC currently does not recommend a test-of-cure after treatment for chlamydia. However, because incidence studies have demonstrated that previous chlamydia infection increases one's probability of becoming reinfecting,<sup>46</sup> the CDC does recommend that previously infected individuals be rescreened at 3 months after treatment for chlamydia.<sup>38</sup>

The choice of the several commercially available NAAT assays available is dependent upon preference of the laboratory, as all of these NAATs are mostly comparable in sensitivity and specificity. All NAATs have vastly higher sensitivity compared to older assays, such as enzyme immunoassay direct fluorescent antibody, culture, and point-of-care assays, and have near perfect specificity. NAATs are highly recommended for screening programs because of their higher sensitivity; the older technologies cannot be used for noninvasive specimens, such as urine and vaginal swabs, which are highly desirable for screening programs.

### TRICHOMONAS VAGINALIS

It is estimated that there are 170 million cases for *Trichomonas vaginalis* in the world and approximately 7–8 million new cases occur every year in the United States.<sup>47,48</sup> *Trichomonas* infections have been associated with adverse birth outcomes, low birth weight, premature rupture of membranes and with HIV transmission.<sup>49–52</sup> The identification and treatment of trichomonas during pregnancy can reduce neonatal transmission and may reduce risk of preterm delivery.<sup>53</sup> Trichomoniasis has primarily been screened for at gynecologic visits in the antenatal or family planning setting by visualization of the trichomonads on wet mount microscopy, but this method is relatively insensitive; culture is more sensitive. A relatively new POC test shows promise with better sensitivity than wet preparation and culture.<sup>54</sup>

At present there is no FDA cleared commercial NAAT assay for trichomonas. Several research PCR assays have been reported and appear to perform with sensitivities >90%; greater sensitivity than wet preparation or culture.<sup>54–61</sup> There is one commercially available analyte specific reagent (ASR) (GenProbe) that is FDA cleared for purchase of reagents, but not in a “kit” format.<sup>61</sup> Clinical trials for FDA clearance of this NAAT assays are underway.

Sensitivity and specificity of wet-preparation microscopy for TV are estimated to be between 50–60% and >90%, respectively, whereas sensitivity and specificity of PCR for TV have been shown to be both >90%, respectively.<sup>58,59,62</sup> A study of multiple etiologies of cervicitis in STD clinics, using both a TMA-based research NAAT<sup>61</sup> and another research PCR-based NAAT<sup>57</sup> for trichomonas, demonstrated an overall prevalence of 15.3% for TV compared with 11.9% using wet-preparation microscopy.<sup>63</sup> Because of the lower sensitivity of the wet-preparation method for diagnosis of TV, a significant percentage of infections may be routinely missed, which allows for sexual transmission to partners, as well as discomfort and possible harmful sequelae in untreated women. In a large study of over 3000 women

attending two STD clinics, Kaydos et al. found a prevalence of 17% using PCR against a reference standard of wet-preparation microscopy and culture.<sup>59</sup> The increased sensitivity of NAAT assays in women above traditional methods of diagnosis such as wet preparation are evidence for more future use of NAAT assays for the diagnosis of trichomonas.

### SYPHILIS (*TREPONEMA PALLIDUM*)

Syphilis screening is important to prevent long term sequelae in infected persons, to prevent transmission to partners, and to prevent congenital infections.<sup>64</sup> Screening is inexpensive and should be performed in all at risk populations. Ideally, it should be performed in the first and third trimester in pregnancy.<sup>38</sup> Syphilis screening is part of routine antenatal care in many countries. Syphilis infection during pregnancy can result in vertical transmission to the fetus (transplacental or intrapartum), with 70–100% transmission rates for primary/secondary syphilis and 40% for early latent syphilis.<sup>65</sup> Congenital syphilis can result in fetal wastage (spontaneous abortion, stillbirth), and birth defects ranging from low birth weight to multi-organ system involvement, such as hepatosplenomegaly and glomerulonephritis, as well as growth abnormalities.<sup>65</sup>

Screening for syphilis in the absence of clinical manifestations is an important part of detection, cure, and prevention of vertical transmission. Variability in clinical presentation of syphilis makes clinical diagnosis unreliable.<sup>64</sup> Thus screening must be performed in the absence of symptoms. The classic painless ulcerated lesion has a diagnostic sensitivity of only 31% and specificity of 98%. Induration is reported to be the single most specific sign, occurring in 47–92% of infected persons. Painless regional lymphadenopathy may occur in up to 80% of patients. There are no clinical manifestations associated with early latent, late latent, or syphilis of unknown duration.

Screening by VDRL or rapid plasma reagin (RPR) has a sensitivity of 80% in primary syphilis, 100% in secondary syphilis; in latency the cardiolipin antibody falls and levels are expected to subside after treatment.<sup>64</sup> After treatment for primary or early secondary syphilis, anticardiolipin antibody levels generally fall to nonreactive over 1–2 years.<sup>64</sup> Treatment of latent or late syphilis is usually followed by persistence of a positive RPR.

The VDRL and RPR tests also have variably compromised specificity, leading to biological false positives. Ideally, individuals with positive RPR or VDRL should have subsequent FTA (fluorescent treponemal antibody absorption test), MHA-TP (Microhemagglutination *T. pallidum*), TPHA (*T. pallidum* hemagglutination assay), or TP-PA (*T. pallidum* particle agglutination assay) testing to confirm the diagnosis of syphilis. High-volume clinical laboratories have begun using automated treponemal tests, such as automated enzyme immunoassays (EIAs) or immunochemiluminescence tests, and have reversed the testing sequence: first screening with a treponemal test and then retesting reactive results with a nontreponemal test. This approach has introduced complexities in test interpretation that did not

exist with the traditional sequence. Patients that are reactive to the treponemal test but nonreactive to the nontreponemal test are a source of confusion as to interpretation.<sup>66</sup> When results are reactive to the treponemal test but nonreactive to the RPR test, persons with a history of previous treatment will require no further management. For persons without a history of treatment, a second, different treponemal test should be performed. If the second treponemal test is nonreactive, the clinician may decide that no further evaluation or treatment is indicated, or may choose to perform a third treponemal test to help resolve the discrepancy.<sup>66</sup>

The CDC, United States, recommends that all pregnant women be screened for syphilis at their first antenatal visit, and in settings where antenatal care utilization may not be regular, women may be screened and treated based on reactive RPR-card test.<sup>38</sup> Additionally, it is recommended that high-risk women be screened again during their third trimester and again at delivery.<sup>67</sup>

## GENITAL ULCERS

Nonvesicular genital ulcers can be caused by syphilis, chancroid, lymphogranuloma venereum, donovanosis, or atypical genital herpes. Due to the lack of adequate diagnostic assays, screening for chancroid, and donovanosis is not usually undertaken in asymptomatic persons. Chlamydia NAAT assays can be used for detection of specimens from symptomatic patients with suspected LGV. All commercial NAAT assays will give a positive result for the LGV serovars of *C. trachomatis*. Rapid screening, such as VDRL or RPR, may be performed to screen asymptomatic persons for syphilis. Chancroid may be considered once syphilis has been ruled out by lack of *T. pallidum* visualization on dark field or by negative serology. Chancroid can be confirmed by identification of *Haemophilus ducreyi* by culture.

There is no molecular test commercially available to test ulcer exudates and culture is not routinely available in most settings. As there are no serologic or other screening assays for donovanosis, the diagnosis is made based on clinical presentation, resolution of symptoms with antibiotics, or microscopic examination. Similarly, lymphogranuloma venereum may be presumptively diagnosed based on clinical presentation; however commercial NAAT assays for chlamydia will be positive for swabs of ulcers caused by the chlamydia LGV serovars. Serology, using the complement fixation test, has been used in the past to diagnose LGV infections but this test is not widely available and CDC no longer recommends it be used.

Serological screening for past or present genital HSV (HSV-1 or 2) is feasible with several assays (Focus Technologies, Kalon) being available, as well as several new POC assays which hold promise to move screening outside a clinic setting.<sup>18</sup> While manufacturer's cut-off index values work well for sera from the U.S., these assays suffer from low specificity when testing sera from sub-Saharan Africa and when HIV infected persons are tested; many researchers recommend using higher cut-off index values.<sup>68</sup> Presumptive diagnosis of lesions or ulcers caused by

HSV is often made on the basis of clinical presentation and definitive diagnosis may be made by HSV cell culture. Research PCRs have been published, but not available commercially.<sup>69</sup> Development of POC assays are underway and may be possible in the near future.

## Possible Sites of Opportunistic Screening for STIs

### ANTENATAL AND FAMILY PLANNING CLINICS

Family planning clinics and antenatal clinics are often sites of high prevalences of STIs and these opportunities for screening should not be missed, especially since untreated chlamydial and other cervical infections are associated with adverse pregnancy outcomes (premature rupture of membranes, chorioamnionitis), and neonatal outcomes (conjunctivitis, prematurity, low birth weight).<sup>49,70</sup> Additionally, despite the well-known association of sexually transmitted infections with acute pelvic inflammatory disease and tubal factor infertility, there is a growing literature on the postinfectious tubal infertility, which results from "silent" pelvic inflammatory disease that is unrecognized by the patient and the physician.<sup>71</sup>

### SCREENING TO PREVENT TRANSMISSION: HIGH-RISK POPULATIONS

The WHO urges the assessment of STI prevalence among population subgroups who are likely to have high rates of disease as a result of their risk behavior.<sup>72</sup> WHO recommended that the minimum assessment for STIs among women at high risk of infection should include syphilis, chlamydia, gonorrhea, and genital ulcers by examination. Screening for STIs decreases the efficiency of transmission through cure and duration of infectiousness with earlier detection and cure. Propagation of infection and probability of transmission can be affected by the degree to which an individual interacts with other individuals.<sup>73</sup> One definition of this concept focuses on geographically stable aggregations of people whose sexual activity permits continued transmission; members of core groups might be responsible for a majority of transmissions.<sup>73</sup> Another definition refers to STI core members as a small proportion of people who experience frequent STIs or often transmit infection.

Identification of core groups for targeted STI screening and prevention can maximally reduce potential spread of disease. For example, Over et al. estimated that the cure or prevention of 100 cases of gonorrhea in non core groups will prevent 426 cases of future gonorrhea over the next 10 years. Further, curing or preventing 100 cases of gonorrhea among core transmitters will prevent 4278 cases of gonorrhea over the next 10 years. This study highlights the importance of identifying persons who are at high risk for acquiring and transmitting sexually transmitted infections to achieve the greatest effect in preventing continued transmission.<sup>74</sup> The STI prevalence among male clients of female sex workers in Thailand has been found to be 6% for chlamydia

and 16% for gonorrhea.<sup>75</sup> A study of female sex workers in China found prevalence of 32% for chlamydia, 8% for gonorrhea, 14% for syphilis, and 13% for trichomonas<sup>76</sup>; and among female sex workers in Japan 19% for chlamydia and for 33% gonorrhea.<sup>77</sup> Thus, screening and treating populations with highly prevalent STIs should receive the most attention.

Risk assessment for targeted screening program may be more cost-effective, in addition to identifying large numbers of infected persons. A study was undertaken to compare the performance of the WHO risk assessment approach to population-specific risk factors identified among women attending an antenatal clinic in Mwanza, Tanzania.<sup>78</sup> Similar to the performance of the WHO algorithm to identify women with cervical infection, the risk scores of factors specific to these women had poor sensitivity and positive predictive value for diagnosing cervical chlamydia or gonorrhea infection, though the theoretical cost per true case detected was cheaper.<sup>78</sup> The authors concluded that while it was of primary concern to develop inexpensive diagnostic assays for these infections, risk assessment was feasible and acceptable.

The major limitation of screening recommendations based on demographic and behavioral factors for the identification of STIs is their lack of generalizability. Sensitivity and specificity of risk factor profiles are dependent on population structure, prevalence of infection, and diagnostic laboratory assays being used. Cost-effectiveness depends on the prevalence of infection, the cost of the method(s) used, and the positive predictive value of the screening algorithm. Therefore, specific guidelines may be inappropriate to apply and difficult to compare between different populations; screening recommendations may be most useful when individualized to a particular population.

### ALTERNATIVE SCREENING VENUES OUTSIDE CLINIC

An advantage of using NAAT assays for the detection of chlamydia and gonorrhea is to be able to move outside a health clinic as well as to use the same sample type for the detection of both chlamydia and gonorrhea. While many outreach screening studies have used NAATs primarily for chlamydia testing, being able to additionally screen for gonorrhea has distinct advantages, especially in populations and regions which have demonstrated high prevalences for gonorrhea in the past.<sup>79,80</sup> These alternative sites for screening programs have included schools, prisons, military personnel, health vans, shopping malls, household surveys, street outreach sites, and teen centers.<sup>81–91</sup> One population study surveyed inner city adults 18–35 years of age in their homes and demonstrated a prevalence of 3.0% for chlamydia, 5.3% for gonorrhea, and an overall weighted prevalence estimate of 7.9% for either infection, the majority of which (94.7%) were asymptomatic.<sup>92</sup> Such studies give public health officials the ability to direct future control efforts towards populations where high prevalences of disease exist in asymptomatic and untreated persons not ordinarily seeking healthcare.

Hospital emergency departments have been the site for screening programs in young adults presenting for reasons

other than reproductive healthcare and have demonstrated high prevalences using urine screening.<sup>79–81</sup> Expanding to wide spread screening programs of sexually active individuals using NAAT assays are supported by recommendations of public health officials.<sup>37</sup> Finally, the effectiveness of expanded screening programs in being able to reduce chlamydia prevalence has been shown in areas where the screening programs have been in existence for an extended time.<sup>82</sup>

### Screening to Prevent Cancer: Human Papillomavirus and Cervical Cancer

It is estimated that nearly 100% of cervical cancers are associated with human papillomavirus (HPV).<sup>83</sup> No significant variation in HPV positivity occurs among countries but rates of cervical cancer vary widely.<sup>83</sup> Longitudinal data from developed countries show decrease in cervical cancer incidence and mortality subsequent to the implementation of program for screening and treatment. However, findings from cervical cancer screening program in developing countries acknowledge the economic and infrastructure barriers to regular and opportunistic cervical cancer screening in these developing countries. HPV testing has augmented the PAP smear screening program in the United States recently. However, in developing countries this option is not feasible. Presently, visual inspection-based approach is recommended as the immediate option in resource limited countries. This recommendation is supported by a recent cost-effectiveness analysis comparing visual inspection methods to colposcopy and HPV testing in low-resource settings.<sup>84</sup> Screening every 1–5 years, as in developed countries, is not a practical recommendation in the developing country settings, and it is recommended to screen women aged 35–50 years at least once before providing repeated screening. A mathematical modeling study comparing cervical cancer screening strategies in resource poor settings supports this recommendation.<sup>85</sup> Compared to more frequent screening strategies, screening women aged 30–59 years once in their lifetime could decrease cervical cancer incidence up to 30%, having the greatest effect per resource utilization.<sup>85</sup>

### Future Directions of Screening: Opportunistic Screening

Early detection and prevention of STIs are cost-effective public health measures. Nevertheless, implementation of screening program throughout the healthcare system and outside is difficult. Major barriers include low priority for STIs, inadequate public health surveillance measures, and inadequate resources. Other barriers include societal sensitivities about sexuality, the traditionally curative rather than preventive focus of healthcare, and healthcare inefficiencies that hinder these programs.

Until recently, available STI screening tests have had poor sensitivity and specificity, or have been too difficult to implement on a wide scale. The development of noninvasive, highly sensitive and specific diagnostic techniques has made identification and

**Table 109.1:** Tests for Screening of Sexually Transmitted Infections

Patient	Method	Tests	Sample type
Women	Microscopy	Gram stain for cervicitis and gonorrhea Gram stain for bacterial vaginosis Wet preparation for trichomonas Cytology (PAP)	Endocervix Vagina
	Culture	Gonorrhea Chlamydia Trichomonas	Urethra, endocervix, rectum, pharynx
	Antigen detection or NAAT	Test for chlamydia or gonorrhea	Urethra, first catch urine, endocervix, vaginal swabs
	Serology	Syphilis, HIV, hepatitis B, hepatitis C	Vein Finger stick (Dried blood spots) Oral fluid (HIV)
Heterosexual men	Microscopy	Gram staining (gonorrhea)	Urethra
	Culture	Gonorrhea Chlamydia Trichomonas	Urethra, pharynx
	Antigen detection or NAAT	Gonorrhea Chlamydia	First catch urine Urethra
	Serology	Syphilis, HIV, Hepatitis B, Hepatitis C	Vein Finger stick (Dried blood spots) Oral fluid (HIV)
Men who have sex with men (MSM)	Microscopy	Gram staining (gonorrhea)	Urethra
	Culture	Gonorrhea Chlamydia	Urethra, pharynx
		Gonorrhea, Chlamydia	Rectum
	Antigen detection or NAAT	Gonorrhea Chlamydia	First catch urine, urethra
	Serology	Syphilis, HIV, Hepatitis B, Hepatitis C	Vein Finger stick (Dried blood spots) Oral fluid (HIV)

NAAT: Nucleic Acid Amplification Tests

[Source: www.aidsctc.org]

treatment of gonorrhea and chlamydia feasible on a population basis.<sup>16,35</sup> NAATs can be used to screen urine for chlamydia and gonorrhea (Table 109.1) with sensitivity of 93–98% and specificity greater than 99%, with a high positive predictive value, even in low prevalence populations. These easily administered tests can be used to screen high-risk populations that are otherwise difficult to assess. Admittedly, the high cost of NAATs technology may be prohibitive, and the source of payment remains an issue.

The advent of these noninvasive screening assays may allow for STI screening in nontraditional venues and among expanded populations. For example, in the United States, school-based screening among adolescents,<sup>46,86</sup> and screening of incoming military recruits have demonstrated significant prevalence of undetected gonorrhea and chlamydia infections.<sup>87,88</sup> Screening among persons entering into detention facilities<sup>89</sup> and routine sex worker examinations may detect a significant number of infections. In addition to expanding access to broader populations, urine-based diagnostic assays may overcome barriers to seeking healthcare for genitourinary symptoms, especially among women<sup>90,91</sup>

## Conclusions

Screening for STIs among asymptomatic persons, as well as those with syndromic presentations is essential to prevent the complications of these infections and further transmission. Screening women seeking antenatal and family planning care may maximally reduce reproductive tract and neonatal morbidity for women and their children. Additionally, screening for STIs among high prevalence population subgroups, such as persons who exchange sex for money or drugs, their clients, and persons with multiple sexual partners, can reduce transmission. The greatest barriers to screening remain in accessing populations in a culturally relevant manner. The availability of new noninvasive specimen types and molecular tests will facilitate testing strategies for screening programs.

Performing population and epidemiologic surveys to identify groups of women and men at highest risk of being infected will be useful to target selective screening algorithms for specific populations. Selective screening of persons at highest risk of

being infected will improve the effectiveness of screening. The integration of routine STI screening and treatment, along with comprehensive programs for education, prevention counseling, and partner notification, will be necessary to affect worldwide increasing trends in STI prevalence.

## Human Papillomavirus Related Genital Neoplasias

### INTRODUCTION

This chapter will largely focus on human papillomavirus (HPV) related genital neoplasias. Human herpes virus 8 (HHV) and associated Kaposi sarcoma is already covered in Chapter 35, while hepatitis B virus (HBV) and associated primary hepatocellular carcinoma is addressed in Chapter 32.

HPV is actually the first pathogen to be recognized as virtually a 100% cause of a specific cancer, that of the cervix. In fact, the story of linking a sexually transmitted agent to cervical cancer started hundreds of years ago, when it was realized that Catholic nuns rarely suffered from this disease.<sup>1,2</sup> Subsequently, around 30 years ago now, and with the tools of molecular biology and sophisticated epidemiological methods, oncogenic genotypes of HPV were proven to be the causative agent of cervical cancer.<sup>3</sup> While there are over 200 genotypes of HPV recognized to date, with well over a hundred already sequenced, around 40 types specifically have tropism for the genital area, with around 12–14 having oncogenic potential.<sup>4</sup> More specifically, it has been shown worldwide, that HPV genotypes 16 and 18 are more virulent, consistently causing around 70% of all cervical cancers,<sup>5–7</sup> and tending to be seen in younger women than with cervical cancers caused by other oncogenic types.

This story is in contrast to many other sexually transmitted infections, where we may know the causative agent, are able to culture the pathogen *in vitro*, have specific antimicrobial agents for treatment, and (apart from HBV, a proportion of cases which are transmitted sexually), despite many attempts, vaccines have not been successfully developed and instituted into public health programs as has occurred for HPV. This is further detailed in Chapter 15.<sup>8</sup> Recognition for the discovery that HPV is the causative agent in virtually all cases of cervix cancer resulted in Professor Harold zur Hausen of Germany being awarded the Nobel Prize for Medicine and Physiology in 2008, bringing the idea that there could be effective vaccines against a cancer into the global public arena worldwide.<sup>9</sup>

### HPV VIROLOGY AND NATURAL INFECTION

The virology, the natural history, and epidemiology of genital HPVs, as well as the clinical manifestations and management are already covered in Chapters 29 and 30, respectively.<sup>10,11</sup> Of note, HPV remains uncultivable by traditional viral culture techniques. Moreover, while genital HPV infection is extremely common, particularly among young, sexually active women, cervical cancer is a relatively rare outcome of HPV infection. Therefore, although the presence of HPV might be a necessary factor, it is not sufficient for carcinogenesis, as only a proportion of women with chronic oncogenic HPV infection will progress over years to develop cervical cancer.

Basically, HPV infects squamous epithelium with expression of various gene products intimately linked to epithelial cell differentiation. HPV infection does not cause a systemic infection; it does not kill the keratinocyte it infects, and it induces no or a poor, slowly developed local inflammatory response. Humoral immunity does not appear to be as important as cell-mediated immunity in clearing HPV infection, but rather is important in protecting an individual from becoming infected. Of note, in natural infection, only around 50% of those becoming HPV DNA positive show a systemic neutralizing antibody response. The remainder of individuals clears infection without developing a measurable antibody response.<sup>12</sup> In addition, of those who become infected with HPV (as detected by HPV DNA), only a small proportion of women will develop a persistent (defined as finding the same genotype on two or more occasions with at least 6 months apart) infection.

Following infection of basal epithelial cells, the viral genome is maintained as a low copy number episome in cells of the basal and parabasal layers and is amplified as the infected cell differentiates and migrates towards the epithelial surface. It is only in the most superficial layers of the epithelium, that late genes encoding for viral capsid proteins (L1 and L2) are expressed and the amplified genomes then packaged into infectious virions, with release at the epithelial surface during cellular desquamation, ready to infect another individual.<sup>13</sup> It is because of this complex interaction of viral maturation with squamous cell differentiation, that HPV

cannot be propagated *in vitro* in cell lines. However, viral nucleic acid can be detected as episomal or integrated genomes by various molecular hybridization assays, as HPV DNA or RNA, and form the basis of detection of HPV infection today. During a productive infection, there is expression of early viral proteins E4, E6, E7 during an infected cell migrating from the basal layer to the epithelial surface, with expression of the major capsid protein L1 following that of E4, and being detectable in poorly differentiated cells at the epithelial surface.<sup>14</sup>

### CELLULAR MANIFESTATION OF HPV INFECTION

Productive HPV infection manifests as low-grade changes cytologically or histologically identified as cervical intraepithelial lesions. If cell mediated immunity fails to induce lesion regression and viral clearance, then persistent infection may result. Really low-grade cervical intraepithelial neoplastic (CIN 1) lesions represent the cytopathic effect of a viral infection and cannot be distinguished accurately from “HPV infection” alone (see Fig. 110.1 for colposcopic findings for HPV infection and in contrast to the normal healthy cervix in Fig. 110.2). It is now realized that it does not necessarily represent a continuum to high-grade disease and cancer, as was once thought. For CIN 1 all early proteins are expressed, the lesions are genetically stable and regression occurs in the majority of cases, with an appropriate host immune response (median duration of CIN 1/LSIL is 6 months).

### ONCOGENICITY

The odds ratios (ORs) for oncogenic HPVs and cancer development are very high, being over 100-fold (281.9 for HPV-16 and 222.5 for HPV-18).<sup>5</sup> This is, in contrast, the elevated OR for cigarette smoking and lung cancer for women which is near 10-fold. Other recognized cofactors that may act in conjunction with oncogenic HPV infection to increase the risk of ICC include cigarette smoking, younger age at first intercourse, high parity, long-term use of oral contraceptive pills, and other sexually transmitted infections (e.g., *Chlamydia trachomatis*, anogenital

Fig. 110.2: Normal healthy cervix.

herpes simplex).<sup>15–17</sup> However, in general, most of these cofactors had ORs in the order of 2, and could reflect residual confounding due to HPV infection and sexual activity.

With oncogenic HPV infection, there can be progression from productive infection to cellular transformation leading to cervical cancer; then the viral DNA can become integrated into the host cell genome (often with deletions in the E2 and L1 genes), resulting in loss of the ability to produce infectious virions. Not all cancers, however, have integrated virus: some having episomal forms, while others mixed integrated and episomal, while some only episomal. In cancers, the viral gene expression is dysregulated, with constitutive expression of the early oncogenes E6 and E7 essential for progression to, and maintenance of malignancy. Oncogenic genotypes of HPV E6 and E7 oncoproteins specifically bind to important host tumor suppressor factors, P53 and retinoblastoma gene product (Rb), respectively, inactivating their function and resulting in abrogation of control of normal cell growth.

### OUTCOME FOR THOSE WITH PERSISTENT ONCOGENIC HPV INFECTION

In a small proportion of women infection remains persistent, remaining unchanged for years. It is persistent infection with an oncogenic virus which puts a woman at risk from development of high-grade dysplasia. Moreover, it has been shown in separate studies, one in Denmark and one in the USA, that those infected with high risk (HR) HPV (as measured by Hybrid Capture 2 test [HC2]) at baseline with a normal Pap and followed over 10 years, the risk of cytological abnormality of atypical squamous abnormalities or worse at 5 years was almost identical at around 17% and for CIN2+ it was 11%.<sup>18,19</sup> Looking at the 10-year positive predictive value of a single positive HR HPV DNA for cytological prediction of CIN3+ it was around 20%.<sup>18,19</sup> When evaluating outcome for those with 2 HR HPV tests at 5 and 10 years, this risk increased from 8.5% (95% CI, 5.7–11.3) to 20% (95% CI, 14.7–24.9), respectively. Of particular note was the value of a

Fig. 110.1: Colposcopic findings for HPV infection.

concurrent high-risk HPV negative test in cytologically normal women: this carried a high long-term negative predictive value being >99% for CIN2+ and CIN3+, suggesting that the screening interval might be safely increased.<sup>18</sup>

In addition, in looking specifically at an HPV test that distinguishes genotypes, detecting HPV 16 and 18 infections from the other potentially oncogenic types may better identify women at risk for developing CIN 3.<sup>20</sup> In a US study, HPV 16 and the phylogenetically related types HPV 31 and 33, consistently conferred the next greatest risks.<sup>21</sup> Similarly in a Danish study of approximately 11,000 women 20–29 years, with follow-up at ~2 years, and as compared with women who were negative for HPV at enrolment, for those with positive results, there was a significantly increased risk at follow-up of having atypical cells (odds ratio 3.2, 95% confidence interval 1.3–7.9), low-grade lesions (7.5, 4.8–11.7), or high-grade lesions (25.8, 15.3–43.6). Similarly, for those women still positive at the second examination, there was a strongly increased risk of low (34.3, 17.6–67.0) and high-grade lesions (60.7, 25.5–144.0). For high-grade lesions the risk was strongly increased if the same virus type was present at both examinations (813.0, 168.2–3229.2).<sup>22</sup>

### THE TRUE PRECURSOR LESION TO CERVICAL CANCER: CIN 3

It is now realized that the true precursor lesion to cancer is high-grade cervical intraepithelial neoplastic lesions (CIN 3) with CIN 2 being a mixture of CIN 1 and CIN 3. Hence, it is now accepted that CIN 2 or CIN 3 can occur *de novo*, rather than result as a progression from CIN 1 lesions. The potential differences between CIN 2 and CIN 3 are further exemplified in the trial based quality control assessment of community pathology, biopsy diagnosis, whereby the authors demonstrated detection of CIN 2 generally had poor reproducibility as compared with that of CIN 3.<sup>23</sup> Moreover, although it is realized that persistent infection with oncogenic HPV is a prerequisite the development of CIN 3, not all of these precursor lesions if untreated would become neoplastic. For example, in a retrospective data from women diagnosed with CIN 3 between 1955 and 1976 in New Zealand, and managed only by punch or wedge biopsy, no ablative treatment *per se* the 30-year cumulative incidence of invasive cervical cancer was 31% (95% CI, 23–42).<sup>24</sup> However, it is currently recommended that all high-grade precancerous lesions receive adequate ablative treatment as we do not know which high-grade lesions will regress and which will progress.<sup>24</sup> In general, CIN 3 is asymptomatic, being noted firstly by abnormal cells on a Pap smear, with abnormal features on colposcopy (see Fig. 110.3). Cervical cancer may present with abnormal bleeding, discharge, or complications of advanced disease. Cervical cancer typically arises in the transformation zone. (The findings on colposcopy can be seen in Fig. 110.4 a and b). Although not well understood, the determinants of HPV persistence and progression are likely to be genetic and/or environmental factors.

## OPPORTUNITY FOR PREVENTION: PROPHYLACTIC HPV VACCINES

The discovery that the HPV late protein gene (L1 gene) which encodes for the outer viral capsid, when expressed in a vector such as eukaryotic cells (*Saccharomyces cerevisiae* yeast cells or *Spodoptera frugiperda* ovarian cells, the natural host for baculovirus) self assemble and produce empty viral capsids into so-called 'viral-like particles' (VLPs) has underpinned the success of the first generation prophylactic vaccines. Basically VLPs effectively mimic a natural HPV viral infection, but are not infectious, given that they do not contain any DNA and virtually trick the immune system into producing neutralizing antibodies<sup>25–27</sup> (see Fig. 110.5a for electron micrograph of the native HPV virions and Fig. 110.5b for the typical structure of VLPs).

\*c+

\*d+

**Fig. 110.5:** (a) Electron micrograph of the native HPV virions (Printed with permission. Courtesy: Dr. Colin Laverty, Sydney, New South Wales, Australia). (b) Electron micrograph of the typical structure of viral-like particles (Courtesy: Prof. Margaret Stanley, Cambridge, UK).

Currently licensed in more than a hundred countries each, are a bivalent (contains VLPs of 16, 18) vaccine as well as a quadrivalent (contains VLPs of 6, 11, 16, 18), both of which have been shown to be efficacious against precancerous lesions (as surrogates to cancer), as well as against persistent infection of the vaccine related types in those previously naive to these genotypes.<sup>28–30</sup>

Moreover, these vaccines are being implemented as public health tools. Where there has been comprehensive and high coverage of the quadrivalent vaccine, with catch-up programs to 26 years, already significant reductions are reported for genital warts in women younger than 27 years, as well as herd immunity being seen in young unvaccinated heterosexual males.<sup>31</sup> In addition, recently reported from a review of Pap abnormalities in Victoria, Australia, a modest but significant decrease in high-grade abnormalities was demonstrated in those women aged <18 years between 2007 and 2009 when the HPV vaccination program was delivered, and compared to the pre-vaccination period.<sup>32</sup>

## Vulvar and Vaginal Cancers

Vulvar cancer is a less common disease, with global incidence rates ranging from 0.1 to 3.5 per 100,000 women for the years 1998–2002.<sup>33</sup> Nonetheless, vulvar and vaginal cancer collectively account for approximately 6% of all gynecological cancers. In contrast to secondary cancer prevention programs for breast and cervical cancers, no screening programs exist for vaginal and vulvar malignancies. The annual progression rate of untreated VIN3 to invasive cancer is at least 10%, whereas for CIN 3 to cancer is approximately 2%.<sup>34</sup> Patients with VAIN have a 2% risk of developing invasive cancer.<sup>35</sup> Diagnosis of vulvar intraepithelial neoplasia (VIN) (see Fig. 110.6a and 110.6b showing the multi-focal nature of disease with areas of hyper- and hypopigmentation) and VAIN is difficult as is their treatment which can be disfiguring, and requires very long term follow-up, as disease recurrence is common.<sup>36</sup>

Vulvar cancer is largely delineated into two distinct clinicopathologic groups based on histology and age of presentation. In older women, the histological type is keratinizing squamous cell carcinoma, which may develop in areas of preceding squamous cell hyperplasia or associated with vulvar dermatoses, particularly lichen sclerosis (see Fig. 110.7). These are not related to HPV infection. In contrast in younger women, the histology is warty, basaloid squamous cell carcinoma, associated with prolonged infection with HPV, particularly type 16<sup>37,38</sup> (see Fig. 110.8). Of particular concern is the changing epidemiology, with increasing number of cases of VIN and vulvar cancer being reported in younger women worldwide.<sup>37,39</sup> Just as cervical cancer, premalignant cellular changes can be found in the vulvar epithelium; these are called VIN. VIN was once graded in three categories from lesser to more severe neoplastic changes (VIN 1, 2 or 3). As low-grade cervical changes, low-grade VIN is really the cytopathic effect of HPV infection and usually resolves spontaneously over time. A small proportion of cases of high-

**Fig. 110.6a,b:** Multi-focal vulval intraepithelial neoplasia (VIN3) with areas of hyper- and hypopigmentation, including involvement of the perianal area in (a) (Printed with permission. Courtesy: Dr. Alice Rumbold, Adelaide, Australia).

**Fig. 110.7:** Large cancerous tumor: rolled edge, friable, bloody, and necrotic with underlying lichen sclerosis (Printed with permission. Courtesy: Dr. Alice Rumbold, Adelaide, Australia).

**Fig. 110.8:** Vulvar cancer in younger woman.

grade VIN (VIN 2 and VIN 3) will progress to invasive vulvar cancer if left untreated. Thus, just as in the cervix, the histological rating system of VIN 1-3 does not necessarily infer a biological continuum. New terminology proposed by the International Society for the Study of Vulvovaginal Disease<sup>40</sup> recommended that the term VIN 1 be dropped, as it does not represent a cancer precursor. In contrast VIN 2 and 3 are considered the preneoplastic lesion of vulvar squamous cell cancer; both lesions express p16(INK4a), a protein product of tumor suppressor gene p16, the aberrant expression of which correlates with the underlying genetic mutations and consequently potential for malignancy. The VIN 2/3 lesions seen in older women (55–85 years of age) are largely differentiated (simple) seen in association with lichen sclerosis and squamous hyperplasia. The undifferentiated VIN associated with persistent high-risk HPV infections, seen in younger women (commonly between the ages of 30 and 40 years), is often multifocal, with a highly variable clinical outcome (see Fig. 110.6). Of note is the strong association with smoking and immunosuppression.<sup>41–43</sup> A proportion of the vaginal cancers are also HPV related (Fig. 110.9).

**Fig. 110.9:** Vaginal cancer.

In clinical trials the prophylactic administration of quadrivalent HPV vaccine was highly effective in preventing HPV-16 or HPV-18-related VIN 2/3 or VAIN 2/3 in women who were naïve to these types prevaccination, with an efficacy of 100%. In follow-up of the placebo arm of the same trials, incident infection with HPV-16 was the most common (6 per 100 person-years). The mean duration from incident infection to the development of VIN 1-3 was 18.5 months (95% confidence interval 13.4–23.6). HPV 16 was observed in 64.5% of VIN 2-3 and 6.5% of VIN 1, last HPV 6/11 was observed in 64.5% of VIN 1, 29% of VIN 2-3.<sup>44</sup> Hence in the long term such vaccines should result in reduced rates of HPV-related vulval and vaginal cancers.<sup>45,46</sup>

## Anal and Penile Cancers

While much is known about oncogenic HPVs being the etiological agents of cervical cancer in women, evidence is gathering to show that oncogenic HPVs, particularly type 16, are strongly associated with some anogenital cancers in men (and women). Specifically, HPV has been linked with 90% of anal cancers, approximately 40% of penile cancers, and around 12% of oropharyngeal cancers.<sup>47</sup> In contrast to cervical cancer, these cancers are less common, with penile cancer being rare and constituting less than 1% of all male cancers, and with an incidence rate recorded in Danish men over a 20-year period in the order of 1 per 100,000.<sup>48</sup> HPV is associated with a proportion of the precancerous high-grade dysplastic lesions of penile and anal intraepithelial neoplasias (PIN and AIN, respectively) (see Fig. 110.10).

Given the greater risk and incidence of anal cancer, and the recognition of progression of high-grade anal intraepithelial neoplasia (AIN 2/3) to anal squamous cell carcinoma in HIV-positive men who have sex with men (MSM),<sup>49,50</sup> some clinicians are recommending screening for AIN in HIV-positive MSM and possibly HIV-positive women (and possibly those with other immunocompromised states such as transplant recipients) using anal cytology, high-resolution anoscopy (HRA), with directed HRA biopsy for definitive diagnosis.<sup>51</sup>

**Fig. 110.10:** Anal intraepithelial neoplasia (AIN) as seen at anoscopy.

However, implementing such screening strategies requires cytologists trained in anal cytology, clinicians trained in HRA, as well as appropriate treatment and follow-up of AIN 2/3. In addition, some ablate AIN 2/3 when it is diagnosed, while others keep it under careful surveillance.<sup>50,52</sup> As there are divergent views with respect to screening for and management of AIN 2/3, appropriate guidelines for care are required.

## VACCINATION IN MEN

There is an established body of data which demonstrates the significant role that male HPV infection contributes to infection and cervical disease in women.<sup>53,54</sup> Hence vaccination of young males with prophylactic HPV vaccination should not only result in prevention of HPV-related disease in men, but also to substantially reduce the disease burden in women.<sup>55</sup>

The quadrivalent vaccine has also demonstrated efficacy against disease in heterosexual males and MSM aged 16–26 years.<sup>56,57</sup> In a randomized, placebo-controlled study ( $n = 4065$ ), vaccine efficacy against any HPV 6, 11, 16, or 18-related external genital lesion was 90.4%, and against genital warts and PIN, it was 89.4% and 100%, respectively. In these young males, vaccination was also effective against persistent infection (85.6%).<sup>57</sup> Further analysis of vaccine efficacy in MSM ( $n = 602$ ; aged 16–26 years) confirms the benefits of HPV vaccination in reducing the burden of anogenital HPV infection and the incidence of HPV-related external anogenital warts (79.0%).<sup>56</sup> After 7 months, seroconversion rates for HPV 6, 11, 16, and 18 were  $\geq 89.5\%$ . Data have also recently been reported at the International Papillomavirus Conference in Montréal, 2010 showing efficacy against 16/18 related AIN.

Hepatitis B virus and hepatocellular carcinoma as well as HHV 8 and Kaposi sarcoma are already covered in Chapters 32 and 35.

# HIV, Sexually Transmitted Infections, and Human Rights

Chris Beyrer • Stefan D. Baral

## Introduction

There is no more private and profoundly personal domain of human activity than sexual life. Violations of sexual rights are among the most egregious of abuses precisely because they affect this most personal realm of life. And because sexual life includes reproduction and the special challenges faced by women in reproduction and in reproductive health; sexual rights are inextricably tied to reproductive rights and to all the contention which have surrounded reproductive issues such as choice, women's autonomy, women's agency in sexual decision making, and individual privacy. It is generally recognized that the universal rights shared by all of humanity have their basis in the essential dignity of our status as human beings.<sup>1</sup> Sexual rights violations then are special threats to human dignity—and they have been misused as such by violators—to degrade, to dehumanize, to strip of dignity. In some conflict settings, sexual violence has been used to terrorize populations through the use of rape as a tool of war, as has been documented in the Former Yugoslavia, in Rwanda, Burma, and, most recently, in DR Congo.<sup>2–5</sup> It is because of the grave nature of these violations that international human rights conventions and laws often provide special protection for sexual rights, reproductive rights, and the sexual health and well-being of women and girls, the most frequent, though certainly not exclusive, victims of sexual rights violations.

The interactions of sexual life, health, and human rights are many and varied, though they have been little studied by the medical professionals. We will explore four contexts in which HIV/AIDS and other sexually transmitted infections (STIs) have been shown to have important associations with human rights contexts, and where examples of population-level interactions appear to be of both public health and human rights significance.<sup>6</sup> These areas are HIV, STIs, and the rights of migrant populations; HIV and STIs in conflict settings; trafficking and coerced sex work; and the special vulnerabilities of sexual minority populations, including men who have sex with men in settings of homophobia and discrimination. To explore these domains the basic components of the human rights framework is essential.

There are several underlying assumptions to the use of the human rights framework. First, it is arguable that human rights abrogation or protection can have profound impacts on the health of individuals, communities, and populations. The evidence base for these interactions is increasingly emerging, but it must be said that human rights have been little studied as health determinants in the STI area, whereas there are more studies, and more interest generally, in the HIV/AIDS literature.<sup>7,8</sup> This is due to both more scholarly interest, the foundation of which has been significantly attributed to the late Jonathan Mann, and to the earlier and intense interest in civil and health rights, and in human dignity more broadly, among affected populations, including gay men in the developed world, and people living with HIV/AIDS more globally.<sup>9</sup>

Second, sexual rights violations are a subset of threats to human dignity—forced, coerced, and related higher risk sexual exposures are correlated with adverse sexual and reproductive health outcomes—including STIs. There are the mechanisms at play in these interactions which need further study, but which nevertheless are clear enough to merit interventions.<sup>10</sup> And finally, responses which include human rights understandings and which seek to improve the rights contexts for people at risk may improve HIV/STI prevention, treatment and control, and provide measurable benefit in human rights contexts for those at dual risk. The challenges of developing and evaluating rights-based interventions and programs for HIV and STI are substantial, but the benefits to individuals, their partners and families, and to communities may be considerable.

## Relevant Human Rights Conventions for Sexual Rights, HIV, and STI

The modern human rights movement had its origins in the same atrocities as did modern medical ethics: the crimes against humanity perpetrated by the national socialists in Germany and their allies during World War II. In response to the Holocaust and the crimes of Nazi doctors, the United Nations General Assembly adopted a visionary set of principles articulating those

fundamental rights of human beings which no state could take away. These were articulated in the 1948 Universal Declaration of Human Rights (UDHR).<sup>1</sup> Delegates representing the United States to the UDHR drafting committee included first lady Eleanor Roosevelt and the great African American scholar W.E.B. Du Bois. Each succeeded in achieving inclusion in the UDHR, respectively, of full and equal rights for women, and full and equal rights for all racial and ethnic minorities. That the United States would endorse the latter principle during the 1940s, when much of the country remained under Jim Crow segregation statutes, illustrates how painfully far so many countries had to go in realizing these universal rights at the time of the Declaration. Nevertheless, the UDHR remains an essential founding document of human rights law and policy. It was an aspirational document, however, not an enforceable treaty. It has no monitoring mechanism and no way to hold violators accountable for rights abrogation.

The UDHR says little specifically in regard to health, but does articulate in Article 25 that all persons have a right to a minimum standard of living, which includes access to healthcare:

“... Everyone has the right to a standard of living adequate for the health and well-being of himself and of his family, including food, clothing, housing and medical care and necessary social services, and the right to security in the event of unemployment, sickness, widowhood, old age or other lack of livelihood in circumstances beyond his control...”

The human rights document which does speak most specifically to the right to health is the 1976 International Covenant on Economic, Social and Cultural Rights (ICESCR), again of the United Nations.<sup>11</sup> Article 12 of the ICESCR refines the right to health with new precision:

Article 12:

1. The states parties to the present Covenant recognize the right of everyone to the enjoyment of the *highest attainable standard* of physical and mental health.

The steps to be taken to achieve the full realization of this right shall include:

- (a) The provision for the reduction of the still-birth rate and of infant mortality and for the healthy development of the child.
- (b) The improvement of all aspects of environmental and industrial hygiene.
- (c) The prevention, treatment, and control of epidemic, occupational and other diseases.
- (d) The creation of conditions which would assure to all medical service and medical attention in the event of sickness.

An amendment to this convention, General Comment 14, was made in 2000, in part to address the special issues raised by the AIDS pandemic.<sup>12</sup> Article 8 of the general comment speaks both

to a more precise explanation of the right to health, and of the right to sexual and reproductive freedom:

The right to health is not to be understood as a right to be *healthy*. The right to health contains both freedoms and entitlements. The freedoms include the right to control one's health and body, *including sexual and reproductive freedom*, and the right to be free from interference, such as the right to be free from torture, non-consensual medical treatment and experimentation.

Two other conventions deserve special mention in regard to sexual rights. The international convention on civil and political rights (ICCPR) of 1976 and the convention on the eradication of all forms of discrimination against women (CEDAW) of 1981.<sup>13,14</sup> The ICCPR generally deals with political rights, including such basic rights as freedom from slavery, torture, persecution, and discrimination. It includes non-discrimination on the basis of sex as a basic right, but did not directly address sexual orientation. In 1994, the UN Human Rights Committee decided *Toonen vs. Australia*, a case in which the Australian State of Tasmania, which had legislation which allowed discrimination against gay and lesbian citizens, was overturned (UNHRC). The UN ruling was that discrimination based on sex, included sexual orientation, and so was in violation of the Convention. This has expanded the right to freedom from discrimination to sexual minority populations within international human rights law.

CEDAW, the 1981 Convention aimed at gender discrimination articulated a set of principles for women and girls in health services.<sup>14</sup> CEDAW states that health services must be consistent with the human rights of women, and that these rights include: autonomy, privacy, confidentiality, informed consent, and choice. These principles are readily seen as in accord with most ethical standards in developed countries. But limits on women's autonomy and privacy, as examples, are markedly common in many settings, where women may have little say in reproductive choice, and even seeking medical care may require male partner or consent of other family members.

## Human Rights and Vulnerability to HIV and STI

How do violations of the rights described actually impact real human beings? How do human rights violations increase vulnerability to STIs or to HIV? We suggest at least three mechanisms by which these interactions may occur.

- (a) *Increased exposure*: Sexual coercion, sexual violence, the use of rape as a tool of war and the kinds of population mixing seen in some conflicts may all increase the likelihood of those suffering rights violations to experience increased exposure risks for HIV and STI.
- (b) *Increased acquisition and transmission*: Treatment delays or gaps, barriers to access to sexual and reproductive health services, and lack of condoms and contraceptive choice may all lead to increased acquisition and transmission risks for STIs.

- (c) *Increased morbidity and mortality*: Barriers to access and to information may increase the disease severity and long-term sequelae of infections once they occur.

## Mapping Domains

Understanding how human rights abuses or protections impact HIV and other STIs is complex. This is an emerging area of investigation, and requires both research and program efforts to further explore. We have identified several domains where these interactions can be explored, but there are doubtless many others ranging from the risks associated with incarceration to the increased vulnerabilities to infection associated with domestic violence that also require research and programmatic responses. Domains where evidence of rights and HIV/STIs will be explored include migration, conflict, sex trafficking, and the vulnerabilities of sexual minority populations.

## MIGRATION

Throughout recorded history, populations have migrated because of economic changes, social change, war, and travel.<sup>15</sup> Though migrants tend to be healthier than the general population because of the “healthy traveler effect”; where measured, migrants generally carry a disproportionate burden of infectious disease including genital herpes, chancroid, lymphogranuloma venereum, donovanosis, and HIV.<sup>16–25</sup> Given that there are currently between 175 and 200 million people documented as living or working outside of their countries of birth, representing approximately 3% of the world’s population, this is a population requiring attention.<sup>26</sup> This number includes approximately 120 million voluntary migrants, people who have chosen to leave their country of origin, and the other 55–80 million are forced migrants, including refugees, trafficked people, and internally displaced people.<sup>15,27</sup> Moreover, there are multiple modes of migration, including permanent migration, temporary migration such as “oscillating” migrants who travel for work and return home periodically, if circumstances allow, and seasonal migration, generally for work in agricultural sectors.<sup>28</sup> Many countries encourage legal, and do little to combat illegal, immigration of a workforce willing to do the type of jobs that their own populace will not, or at a salary level below the living wage.<sup>29</sup> However, in return the receiving country should be compelled to offer and develop socioculturally appropriate HIV/STI prevention strategies, or at least translate existing education programs to the local languages of the migrants.<sup>27</sup> Recognizing the health needs of migrants, the UN General Assembly adopted the “International Convention on the Protection of the Rights of all Migrant Workers and Members of their Families” in December of 1990.<sup>30</sup>

Article 43 states:

Migrant workers shall enjoy equality of treatment with nationals of the state of employment in relation to:

- (a) Access to educational institutions and services subject to the admission requirements and other regulations of the institutions and services concerned;

- (b) Access to vocational guidance and placement services;  
(c) Access to vocational training and retraining facilities and institutions;  
(d) Access to housing, including social housing schemes, and protection against exploitation in respect of rents;  
(e) Access to social and health services.

To date only 22 countries have ratified the convention, with an additional 10 having signed it. The countries that have ratified and signed the convention tend to be the source or origin countries for migrants and thus these protections only apply to about 2–3% of the global migrant population.<sup>31</sup> Unfortunately, there are far more published examples of governments ignoring the needs of migrants resulting in heightened STI and HIV risk.

Thailand has been heralded as an early adopter of evidence-based HIV and STIs interventions targeting heterosexual and parenteral transmission. In response to knowledge, attitude, and perception (KAP) surveys in the early 1990’s that demonstrated low levels of understanding regarding HIV and STIs transmission routes and high-risk practices, the Thai government developed and operationalized a comprehensive education and awareness program. In just a few years, repeat KAP surveys characterized the success of this programming with much higher HIV and STI-related knowledge in the general population. However, studies completed around that time and since have shown that these messages were not disseminated to the more than 1 million Burmese migrants in western and northern Thailand living outside of the refugee camps.<sup>32</sup> Specifically, more than 95% of both male and female adult Thai nationals understand the role of condoms in prevention the transmission and acquisition of HIV and other STIs. However, less than 60% of male Burmese migrants and less than 15% of female Burmese migrants can answer these same questions correctly ( $p < 0.05$ ). Moreover, 68% of male and 40% of female Thai nationals reported regular condom usage in comparison to 12% of male Burmese migrants and 1.4% female Burmese migrants ( $p < 0.05$ )<sup>32–35</sup> (Fig. 111.1). Qualitative work identified five barriers to information and healthcare among

Barriers to information, health care: Language, legal, physical, economic and political.

PHR/JHU: Thailand's failure to provide access to services violates Thai law AND undermines national HIV and STD programs

**Fig. 111.1** Burmese migrants and barriers to access in Thailand.<sup>32–34</sup>

Burmese migrants: language, legal, physical, economic, and political.<sup>32</sup> Physicians for human rights (PHR) concluded that Thailand's failure to provide access to reproductive health and preventive services violated Thai law and undermined national HIV and STD programs.<sup>35</sup>

After the collapse of the Soviet Union, there was a sharp increase in population mobility, mixing, and migration, and consequent epidemics of infectious diseases such as syphilis and HIV-1.<sup>36,37</sup> There has been a sharp increase in both internal and external migration of sex workers across the former Soviet Union (FSU) with increasing involvement of organized criminal syndicates.<sup>38</sup> Sex workers are believed to play important roles in the emerging sexual risk component of the FSU epidemics, but the data are sparse and research in this area fraught with logistical and human subjects protection challenges.<sup>38</sup> In 2005, our group studied 483 female sex workers in Moscow and found relatively high prevalence rates of STIs including a syphilis rate of 15.8%; *chlamydia trachomatis*, 18.4%; gonorrhea, 2.9%; and HIV, 3.1%. Overall, 34.6% of women had biological evidence of any STI—and after adjusting for age, sexual practices, and education level, a prominent risk factor was determined to be the limited access to healthcare (aOR: 2.1, 95% CI 1.2, 3.5,  $p < 0.01$ ). Since many of these women migrated to Moscow from other states of the FSU, they were not granted a Moscow residency permit which has increased their risk of contracting STIs.

The lack of access to appropriate or evidence-based care in settings where those services are available to the host population is a common determinant of STI and HIV risk for migrant populations. This risk has been demonstrated for Mexican migrants to the United States, Nepalese migrants to India, rural to urban migrants across China, and beyond.<sup>16,21,25,39,40</sup> To counteract this determinant of HIV and STI risk, the WHO has designed a framework for a public health approach for migrants. The essence of this framework is to uphold article 43 of the International Convention on the Protection of the Rights of all Migrant Workers and Members of their Families; avoid disparities in health status and access to health services between migrants and the host population. Secondly, the destination country should uphold the rights of the migrant by limiting discrimination or stigmatization, and removing impediments to migrants' access to preventive and curative infectious disease interventions.<sup>27</sup> Arguably, these two actions would protect the health of the migrant populations, but also the host population given the overlap of social and sexual networks between these two populations.

## CONFLICT AND STI & HIV VULNERABILITY

More people died in conflict settings during the 20th century than throughout recorded history and the 21st century seems to be outpacing its predecessor.<sup>41</sup> Understanding the relative contribution of sexually transmitted infections to conflict-related morbidity and mortality has proven complex. Rights abuses, including violations of the rules of war and the deliberate targeting of civilian populations have long been a feature of war, and in

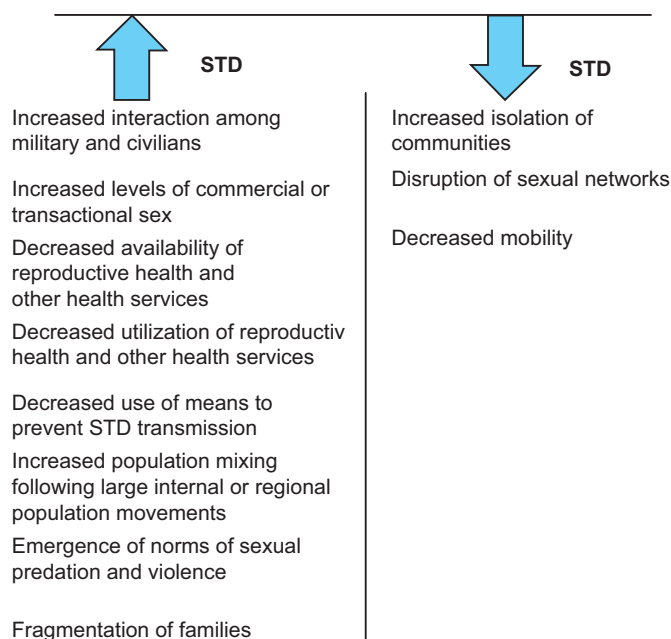

Fig. 111.2 Conflict and STDs.<sup>48</sup>

particular of the kinds of civil conflicts which have generated “complex emergencies,” where humanitarian crises unfold in the context of conflict, exposing civilians to a wide array of abuses. There are a number of structural drivers of sexual and gender-based risks for STI and HIV that may increase transmission risks associated with increased interaction between military and civilians (Fig. 111.2). In the African context, a recent review demonstrated that military personnel tend to have higher HIV prevalence rates than their civilian counterparts.<sup>42</sup> Influx of military personnel has long been associated with increased levels of commercial, transactional, and survival sex.<sup>43</sup> Women and girls are also more likely to engage in survival sex in conflict settings where unemployment is rampant, and most forms of economic productivity interrupted.<sup>44</sup> These types of sex, especially in the context of conflict settings, tend to be associated with lower rates of condom usage than in comparable non-conflict settings.<sup>45</sup>

Conflict can also interrupt health services more broadly, reducing access to care. In the armed conflict of Cote D'Ivoire, between 25% and 55% of the population was displaced depending on region of residence.<sup>46</sup> And in turn over 3 years Cote D'Ivoire experienced a 95% reduction in doctors (234–11); and nearly 80% decrease in allied health professionals (1319–273). Hence, the provision of comprehensive healthcare services in conflict settings is in the very least disrupted, but more commonly is indefinitely suspended.<sup>47</sup> While this tends to include such basic public health interventions as pediatric vaccinations, it also mitigates the availability of reproductive health services to the afflicted population. Condom and lubricant distribution, HIV testing and counselling, and syndromic treatment of STIs are all services affected by conflict.<sup>48</sup> Lastly, antiretroviral management of known HIV-seropositive patients is intermittently disrupted

causing increased morbidity and mortality, with the potential of increased incidence of drug-resistance strains of HIV.<sup>49</sup>

Rape of women and girls has been long a reality of conflict—and in recent conflicts, rape, itself, has been used as a tool of war. Under the convention on the eradication of all forms of discrimination against women (CEDAW) and the convention on the rights of the child, rape is both an egregious human rights abuse, and a violation of the rules of war.<sup>1,14,50,51</sup> In civil wars, such as in the democratic republic of Congo and Darfur, rape has been reported by thousands of women. And these sexual acts have been so violent as to have caused recto-vaginal fistulae in the victims.<sup>52</sup> However, the most extreme example in history is the rape of 250,000 women and girls in just a few months during the Rwandan civil war perpetrated by the Rwandan army and Hutu extremists in 1994. Subsequently, tens of thousands of HIV-positive women reported these rapes as their primary risk factor for HIV acquisition. Though antiretroviral coverage has increased over the last 15 years, the HIV-related morbidity and mortality among these women has been unacceptably high.<sup>53,54</sup>

Recent mathematical models have been developed to characterize the relative contribution of rape during war and found that rape alone is likely not directly responsible for significant increases of HIV/STIs in the general population prevalence. Anema et al. developed models assuming a conflict setting where 15% of women were raped by perpetrators with eight times the prevailing population HIV prevalence and four times the transmission rate per coital act and found only a very modest increase in absolute HIV prevalence of 0.023%.<sup>55</sup> These analyses were informed by whatever raw data were available from conflict settings including Somalia, Sudan, Sierra Leone, among others. The authors conclude that many militias are made up of young men and boys from rural areas, and may not have a high HIV prevalence. However, these models do not take into account secondary effects of rape-mediated HIV transmission including vertical transmission, heterosexual infection of these women's primary male partners, who may have concurrent partnerships, and finally increased susceptibility to HIV acquisition by future partners mediated by genital ulcerative diseases. Whatever the contribution to overall HIV prevalence at population levels, the impact of these crimes against women and girls is profound at the individual, family, and community levels. And such crimes do not need disease associations to be prosecuted. Indeed, part of the case against Charles Taylor, former leader of Liberia, is the use of rape as a tool of terror by forces he supported in the civil conflict in Sierra Leone, and for which is currently standing trial for crimes against humanity by the Special Court for Sierra Leone in The Hague.<sup>56</sup>

Adding to the complexity of assessing the role of conflict in the spread of HIV and STIs is that these contexts can also paradoxically mitigate HIV-related risk. Sexual networks are disrupted, communities are isolated, and mobility limited.<sup>48</sup> These determinants may act to significantly limit HIV spread in the context of generalized epidemics during times of war.<sup>57</sup> But whatever population-level protection from HIV exists during

Fig. 111.3 HIV/AIDS studies initiated, DRC, 1982–2004.<sup>59</sup>

wartime, it is arguably outweighed by the immediate increase in population mobility and mixing during the reconstruction phase following the end of conflict.<sup>58</sup>

As described in this section, history is full of examples of the failure of sustained healthcare delivery in conflict zones. A retrospective analysis of HIV/AIDS studies initiated in the Democratic Republic of Congo demonstrated that similar to its neighbors, there was a significant amount of research that took place in the 1980's. However, with the onset of a sustained war in the late 1980's and 1990's, little research has been done there since (Fig. 111.3). And the limited work that has been done has focused on the effects of conflict on HIV/AIDS service delivery.<sup>59</sup> These prolonged conflicts have necessitated the development of practical and evidence-based HIV/AIDS interventions and research strategies for these settings. Mills et al. have shown that it is possible to deliver sustained antiretroviral medications to HIV-infected people in Northern Uganda and achieve compliance rates as in comparable low-income group, but non-conflict, settings.<sup>60</sup> In this study, their group delivered combination antiretroviral medications to 1625 people, 14 years and older, with 92.2% (1403/1521) of patients with adherence data having more than 95% adherence. Another example of service delivery in conflict zones are the mobile obstetric medics (MOM), which provide antenatal care, family planning, syphilis screening, among other health services in Eastern Burma.<sup>61</sup> These examples highlight both the possibility and necessity of the continued provision of comprehensive and sustained health and preventive services during wartime and in conflict zones, above and beyond emergent care.

## TRAFFICKING AND COERCED SEX WORK

Trafficking in persons violates universal human rights to life, liberty, and freedom.<sup>62</sup> It has been defined as a “modern form of slavery,” by Human Rights Watch (HRW, 1996). The subset of trafficking which includes trafficking for work in commercial sex is a particularly heinous form of slavery and one with potential grave, if difficult to study, health implications. The United Nations Palermo Protocol of 2000, “Protocol to Prevent, Suppress and Punish Trafficking in Persons, Especially Women

and Children, Supplementing the United Nations Convention Against Transnational Organized Crime,” addresses trafficking, including sex trafficking and related forms of sexual exploitation, and is now widely used in the field.<sup>63</sup>

Palermo defines trafficking in persons as:

The recruitment, transportation, transfer, harboring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for purpose of exploitation.

Exploitation shall include, at a minimum, the exploitation of the prostitution of others or other forms of sexual exploitation, forced labor or services, slavery or practices similar to slavery, servitude or the removal of organs.

The evidence base for the health effects, including impacts on HIV and STI, for sex trafficking is modest but growing.<sup>64–67</sup> In a series of important papers among women and girls trafficked between Nepal and India, Gupta et al. and Silverman et al., have studied the HIV and STIs associations with trafficking in this extensive prostitution context. In a 2007 *JAMA* paper, they reported that girls trafficked into sex work prior to age 15 years were at markedly higher risk for HIV infection than those trafficked at 18 years or older, with an adjusted odds ratio (aOR) of 3.7 (95% CI = 1.32–10.34).<sup>68,71</sup> These younger trafficking victims, albeit a small sample ( $n = 33$ ) had over a 60% prevalence of HIV infection. Having been trafficked to Mumbai, as opposed to other destinations in India, was associated with a markedly higher aOR for HIV infection, as was longer duration of forced prostitution, suggesting structural factors like play key roles in the risks for HIV among these girls and women.

Zimmerman and Watts have done considerable work on sex trafficking into Europe.<sup>70</sup> They recently reported on a series of 192 women in post-trafficking services and found very high levels (greater than 95% of all women interviewed) of reporting of violence and coercion while in trafficked circumstances, and high levels of post-traumatic stress disorder (PTSD) among survivors—suggesting that HIV and STI are part of a larger continuum of health threats for these women and girls.<sup>71</sup>

There is no debate that sex trafficking is a grave threat to the health and well-being of its victims. But there is considerable debate about the scale and scope of this health threat, and about the relationship of sex trafficking to sex work more broadly.

In an investigation conducted by our group in collaboration with Physicians for Human Rights on trafficking among Burmese and Ethnic Minority women and girls in Thailand, we found that trafficking was much less common than had been reported in the lay media, and that sex trafficking was a relatively small component of trafficking from Burma, involving some few hundred cases per

year, while labor migration involved hundreds of thousands of Burmese over the same time period.<sup>34</sup>

The relationship of sex trafficking to sex work, more broadly, has been an intensely contested area for the public health community.<sup>72,73</sup> The issue emerged in the U.S. political sphere with the inclusion of a controversial “Prostitution Pledge” in the initial legislation creating both the President’s Emergency Plan for AIDS Relief (PEPFAR) program and the Office of the Global AIDS Coordinator (OGAC). The language deliberately merged sex trafficking with prostitution writ large, and required all PEPFAR grant recipients to adopt a policy of opposing sex trafficking and prostitution in order to qualify for US federal AIDS funding. There was no debate around opposing sex trafficking, clearly seen as both a crime and severe human rights violation by all relevant parties. The controversial issue was the conflation of all sex work with sex trafficking. In a widely publicized refusal to comply with this policy, and with its conflation of sex work and trafficking, the Government of Brazil publicly rejected an offer of some 40 million US\$ in HIV/AIDS funding, stating that sex workers were an integral part of Brazil’s HIV program, and that the government could not embrace a policy opposing its own constituents.<sup>72</sup> The prostitution pledge was subsequently the subject of two first amendment suits against the Bush administration.\*

How does human rights law and policy view this debate? The Palermo protocol asserts that “The consent of a victim of trafficking shall be irrelevant.” This is an important assertion, since both public health actors and sex worker advocacy groups have attempted to define voluntary or consenting participation in commercial sex as inherently different from coerced sex work. All sides of this sometimes contentious debate agree that trafficking is a crime and a rights violation, and there is broad global consensus that sexual exploitation of children is again both criminal and a rights violation. But while these distinctions are important, and have important health implications, from the perspective of trafficking in persons as a violation of human rights law the protocol is clear: even if a woman consents to be trafficked for sex work—it is exploitation which defines trafficking, not the consent of the victims.

A great deal more work needs to be done on the best practices for identification, treatment, and care of victims of trafficking. Their sexual health is clearly an important issue, but their psychological and emotional health needs are clearly vital as well.

## SPECIAL VULNERABILITIES— MSM AND OTHER SEXUAL MINORITIES

Homosexuality remains criminalized in over 80 member states of the United Nations, with punishments ranging from jail time to the death penalty (Fig. 111.4). And with the ongoing arrests and imprisonment of gay men and other MSM in Senegal, Nigeria, Cameroon, Iran, and, increasingly, Iraq, these laws continue to be enforced. MSM are at high risk for HIV infection in

\*One of the authors of this Chapter, CB, wrote a technical brief in support of the claimants for one of these cases.

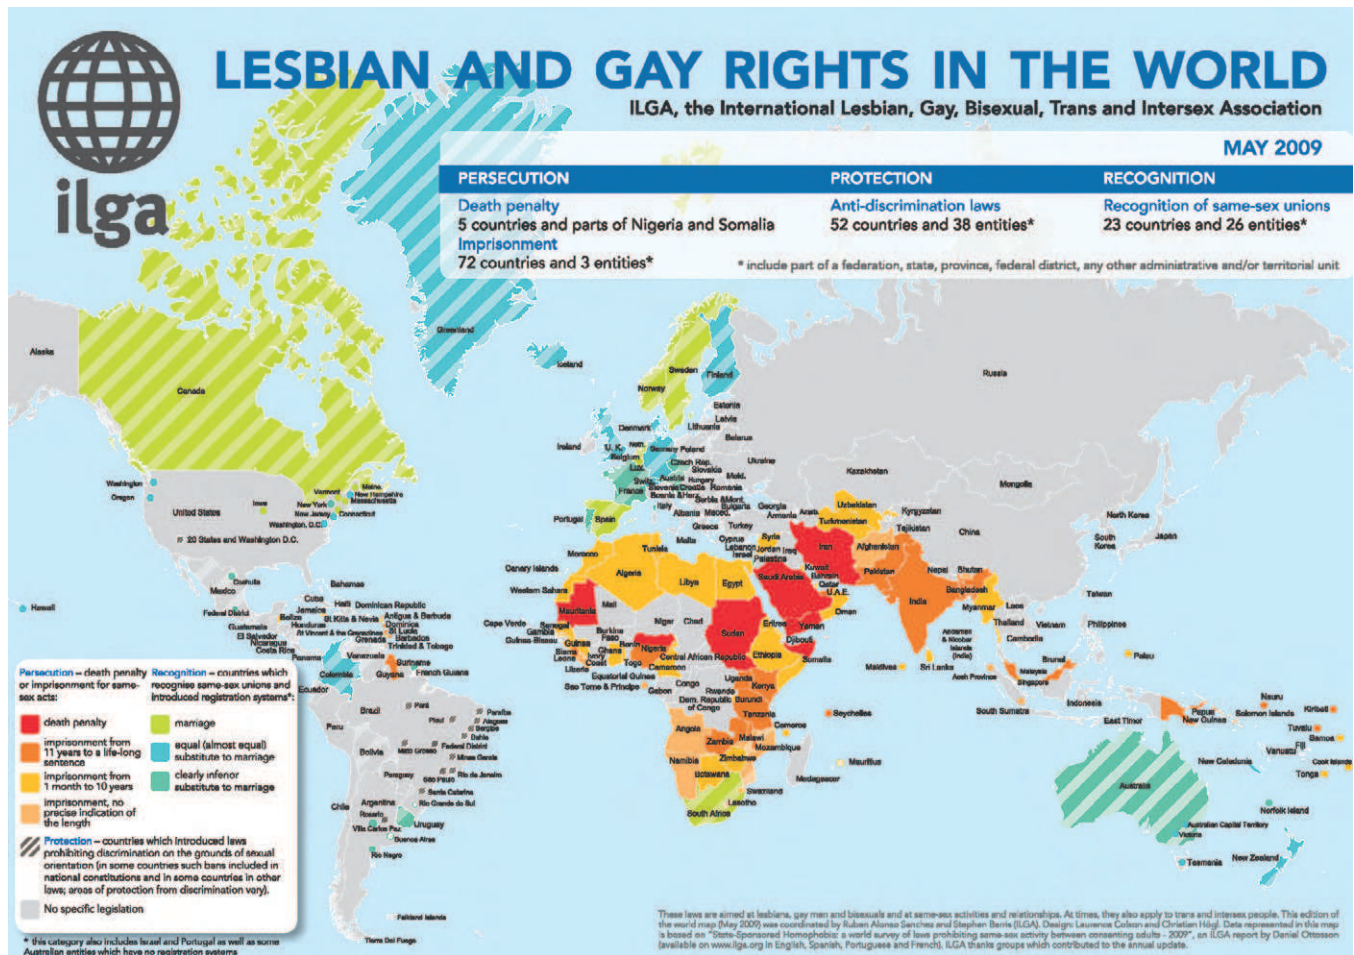

Fig. 111.4 Global summary of laws criminalizing same-sex practices as of May, 2009.

nearly every context where the virus has been described.<sup>74</sup> There are individual level risk factors for HIV and STI transmission including unprotected anal intercourse, or genital ulcerative diseases that likely transcend geography. However, higher order and more structural risk factors, such as criminalization, and other limits on human freedom and bodily integrity likely play roles in structural risks for HIV and STI as well.<sup>75</sup> Repressive legal contexts and pervasive social stigma can limit access for these men to appropriate STI and HIV services, including prevention, treatment, and care. And in such settings, healthcare workers may be part of the problem, as has been recently been demonstrated among MSM in three African countries, where MSM who disclosed their sexual orientation to healthcare workers were more likely to report having been blackmailed.<sup>76,77</sup> Stigma-targeting MSM and transgendered (TG) people can be extreme and can be life-threatening—as is currently the case with ongoing executions of gay men in Iraq and with violence and murders conducted with impunity throughout the world.<sup>78</sup> In these environments, even if there were funding for state-of-the-art comprehensive HIV prevention and care packages for MSM, they would likely be of limited value, since men in such settings are quite justified in not seeking care.

"In countries without laws to protect sex workers, drug users and men who have sex with men, only a fraction of the population has access to prevention. Conversely, in countries with legal protection and the protection of human rights for these people, many more have access to services. As a result, there are fewer infections, less demand for antiretroviral treatment and fewer deaths. Not only is it unethical not to protect these groups; it makes no sense from a health perspective. It hurts all of us."

*Ban Ki-moon, Secretary-General of the United Nations, August 2008.*

In many of these settings, criminalization of homosexuality has been coupled with ignorance of the risk for HIV infection and an almost complete lack of attention to oropharyngeal or anorectal STIs among gay men and other MSM. According to a review of the 2008 UNGASS reports on indicators of HIV among MSM, nearly half of those low and middle income countries that submitted reports did not have data on a single indicator of HIV rates or risk among MSM.<sup>79</sup> Yet, recent studies continue to characterize high burden of HIV and STIs, including HSV-2 infection, syphilis, and anal HPV among MSM in these same countries where the HIV epidemic was traditionally thought to be driven by high-risk heterosexual, vertical, and occasionally parenteral transmission.<sup>80</sup>

There is a powerful human rights argument for why anti-sodomy laws should be repealed; nearly all of the countries that criminalize homosexuality are signatories to the International Covenant on Civil and Political Rights which as of 1994 prohibits discrimination against sexual minorities.<sup>81</sup> And the International Covenant on Economic, Social, and Cultural Rights, also ratified by many of these countries, promises the highest attainable standard of health to all people, including sexual minorities.<sup>12</sup> The recent example of India overturning section 377 banning same-sex sexual practices in July of 2009, highlights the value in reminding these countries of their obligations to their citizens.<sup>82</sup> However, given different sociocultural norms, the human rights argument should be partnered with a public health argument; where stigma against homosexuality is both the rule of law and a sociocultural norm, it is nearly impossible to enact a comprehensive plan mitigating the harms of STI and HIV among MSM.

Our group recently completed the first assessment of human rights abuses for MSM in Malawi, Namibia, and Botswana; three countries which criminalize homosexuality. Human rights abuses among MSM in the study sample were prevalent across all three countries. Between 5% and 10% of the study participants, depending on the site, had been denied housing in the past for reasons other than the ability to pay. Being afraid to seek health services because of sexual orientation was reported by 17.6% (35/199) in Malawi, 18.3% (40/218) in Namibia, and 20.5% (24/117) in Botswana. While having been denied healthcare was less common with a pooled prevalence of 5.1% (27/533), disclosing sexual orientation to a healthcare worker was significantly associated with having been denied healthcare (OR 4.2, 95%CI 1.9–9.3). MSM reported being afraid to walk down streets in their own community most commonly in Botswana, but also to a lesser extent in Malawi and in Namibia ( $p < 0.05$ ). Overall 42.1% (222/527) of MSM answered yes to any of these markers of human rights violation. Of the total sample, 12.2% (65/533) indicated that they had been physically abused by a government or police official, with the highest rates in Namibia ( $p < 0.05$ ). Finally, 11.4% (61/534) of the sample reported ever having been raped by another man, with similar rates across the three sites. Blackmail or extortion on the basis of sexual orientation or behavior was quite prevalent in the sample with an overall rate of 21.2%. In the pooled analysis, univariate associations with blackmail included having either paid or received money or gifts for casual sex ( $p < 0.01$ ); having told a member of the family of one's sexual orientation ( $p < 0.01$ ); and having told a clinic or healthcare worker of one's sexual orientation ( $p < 0.05$ ), and not having had an HIV test in the preceding 6 months ( $p = 0.06$ ). Multivariate analysis was completed adjusting for these covariates and blackmail was significantly associated with having taken part in transactional sex (aOR 2.5, 95%CI 1.6–3.8), not having had an HIV test in the last

6 months (aOR 0.56, 95%CI 0.3–1.0), having disclosed same sex behavior to a member of the immediate or extended family (aOR 2.3, 95%CI 1.4–3.6), but not to healthcare workers (aOR 0.9, 95%CI 0.5–1.6).<sup>76</sup>

These structural barriers to available healthcare services will limit the efficacy of any interventions targeting individual level determinants of sexual infections among MSM and must arguably, be mitigated to effectively decrease HIV incidence and to treat curable STIs.<sup>25</sup> We would argue that the abolishment of anti-sodomy laws could serve to jump start a renewed, coordinated, and inclusive global HIV prevention effort where resources are allocated based on evidence-based need and not moral or religious principle. A roadmap for such an effort would consist of a multi-level approach addressing both individual and structural drivers of HIV and STI risk among MSM. And a comprehensive framework for addressing human rights standards for issues of sexual orientation and gender identity has recently been developed and termed the Yogyakarta Principles.<sup>83,84</sup> Moreover, in 2009 UNAIDS published an action framework providing a map for countries to adopt universal access for MSM and transgender people. In this document, the UN delineates leadership roles for the various UN agencies in this revived effort—with the UN development program (UNDP) being the global lead for matters of sexual diversity.<sup>85</sup> Now that these roles have been defined and a mandate delivered, it is time to move forward on protecting the rights and health of these men.

## Ways Forward

While the domains discussed here are diverse and the challenges faced by vulnerable populations in conflict, trafficking or repressive environments for migrant or sexual minorities differ markedly as well, several themes do emerge when exploring HIV and STIs within human rights frameworks. It is clear that sexual rights violations can and do impact vulnerability to sexual health threats, and that those who suffer from abrogation of sexual rights are at increased risk of disease acquisition, lack access to care, and face disproportionate burdens. It is also arguable that a focus on improving the rights context for vulnerable individual and groups has tangible health benefits—although here the evidence base is less strong. We would argue that human rights considerations need to be understood as social determinants of disease, and studied as such. This has the potential for benefit on several fronts—addressing the health needs of those most at risk, and attempting to mitigate the harms of rights abrogation in this most compelling of private domains. The field of sexual rights and health is in its infancy, yet the call for human dignity—for just treatment of those in conflict, in the misery of trafficking or the repression of discrimination based on gender and sexual orientation is one we cannot and should not ignore.

### Summary

Sexual rights violations can have profound impacts on the health and wellbeing of individuals and communities. A number of international rights conventions and treaties address sexual and reproductive health and rights, though biomedical research on the intersection of rights and sexually transmitted infections has been limited, largely to associations with HIV infection. Several domains have been identified as most relevant for understanding the impact of rights abrogation on STIs and HIV disease transmission and impact. These include HIV and STIs in conflict, in migration, in relation to sex trafficking, and the special vulnerabilities and rights abrogation-associated sexual minorities, especially men who have sex with men. There is an urgent need for greater recognition of the role of sexual rights violations as social determinants of disease, and for an expanded research agenda attempting to improve both the sexual health and human rights of those facing these inter-related challenges to well-being.

## Introduction

Obviously, much of what we know or need to learn about infectious diseases cannot be obtained by the study of the infection in humans, particularly with respect to the basic mechanisms of pathogenesis, pathology, and the host response. Moreover, the complexities of a disease and interaction of the organism with its host cannot be modeled accurately *in vitro*; therefore, it is essential to have an animal model of the infection in order to gain these insights. Fortunately, there are a number of excellent animal models for several sexually transmitted infections; but as in most animal models, there are various advantages and disadvantages associated with each. In some cases, the actual etiologic agent of the human disease either is not infectious for animals or does not produce disease exactly as in the human; nevertheless most models, if used to answer appropriate questions, can and have provided valuable information. Indeed the critical factor is that a given model only be used to address a question for which it is most suited. In this chapter, we will present summaries of the various animal models for sexually transmitted infections and how each relates to or resembles the human disease and the nature of the host response to the infection; but we will also address those applications or research questions for which the models are likely to result in meaningful information.

## Chlamydial Infection

Chlamydia researchers have been fortunate in that there are three different animal models for genital infections, which allow for a range of research opportunities and the potential for comparison. Chlamydia are ubiquitous organisms infecting a variety of mammalian hosts and although in mammalian hosts other than human, the infection targets the gut, it has been possible to use the natural organism to infect genital sites. However, a caveat of chlamydial infections is that they tend to be very host-specific and attempts to infect smaller animals with *C. trachomatis* have met with varied success. A number of more detailed reviews of animal models for chlamydial genital tract infections have been published previously.<sup>1-5</sup>

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Non-Human Primate

Not unexpectedly, infection of the non-human primate with chlamydiae most closely resembles human genital tract disease, and the model is made even more relevant by the ability to infect the animals with the human agent. Nevertheless, the non-human primate suffers the disadvantage of being prohibitively expensive and inconvenient for many basic research studies. Several different species of non-human primates have been infected in the female genital tract with *C. trachomatis*, including pig-tailed macaques (*Macaca nemestrina*),<sup>6,7</sup> grivet monkeys (*Chlorocebus aethiops*),<sup>8-10</sup> cynomolgus (*Macaca fascicularis*),<sup>11</sup> rhesus monkeys (*Macaca mulatta*),<sup>11</sup> marmosets (*Callithrix jacchus*),<sup>12</sup> and baboons (*Papio* sp.).<sup>13-14</sup> The only reported studies of infection of male non-human primates was a report of urethral infection of baboons by DiGiacomo et al.<sup>15</sup> and chimpanzees by Jacobs et al.<sup>16</sup>

The most commonly used non-human primate model is the pig-tailed macaque. Using serovar D, monkeys were inoculated in the cervix with  $10^6$  inclusion-forming units (IFU) and the course of the infection monitored.<sup>17</sup> The animals remained infected in the cervix for 6–15 weeks following a single inoculation, although infection of the fallopian tubes and tubal disease could not be demonstrated. Nevertheless, the observation of this rather lengthy lower genital tract infection appears to model human infection very well, which is also felt to be several weeks in length. This is in contrast to mice and guinea pigs in which the infection is much shorter at 3–4 weeks. Because it did not appear that cervical inoculation would result in ascending infection, Patton and colleagues inoculated serovars E and F directly into the fallopian tube and then monitored the infection at 1 week intervals by laparotomy with the collection of swabs and biopsies for histopathologic examination.<sup>6</sup> On days 7 and 14, marked edema and swelling of the fallopian tubes was observed, returning to normal size by day 35. In two of six animals, exudate was noted. Histopathologic examination showed initially a few

polymorphonuclear leukocytes in the mucosa and sub-mucosa at day 7 but progressed by day 14 and 21 to increased inflammation with lymphocytes (primarily T cells), plasma cells and mast cells. A similar response was reported in grivet monkeys as well.<sup>10</sup> Upon necropsy, there did not appear to be any evidence of scarring or tubal obstruction in the fallopian tube. Chlamydiae could be isolated for 1–2 weeks following inoculation; thus while the infection in the fallopian tube appears to be markedly shorter than in the cervix, the pathologic response does resemble very closely what has been observed in humans.<sup>18,19</sup>

Actual ascending infection to the fallopian tubes with *C. trachomatis* was demonstrated in pig-tail macaques after repeated cervical infection<sup>7</sup> and in grivet monkeys by a single inoculation through the cervical os.<sup>10</sup> While mild chronic salpingitis developed in 2 monkeys in the former study, one animal did develop peritubal and periadnexal scarring after reinfection with one fallopian tube becoming obstructed. These data demonstrated that ascending infection resulting in tubal obstruction could indeed be demonstrated in the non-human primate model, although repeated infections appear to be necessary; thus, the data from these two studies support observations in humans that infertility is more likely to occur following repeated infections. Histopathologic examination of the salpinx in both studies revealed numerous plasma cells and lymphocytes analogous to observations in women and suggestive that the etiology is associated with the adaptive immune response.<sup>7,20</sup>

An alternative non-human primate model has been developed in both cynomolgus and rhesus monkeys in which salpingeal tissue is removed from the animal and autografted into subcutaneous pockets on the anterior abdominal wall with as many as eight pockets in cynomolgus and 20 pockets in rhesus monkeys.<sup>11</sup> As a result of the graft, the oviductal tissue is able to retain its morphology and the individual pockets can be inoculated with chlamydiae. While the usefulness of this model is limited because of the subcutaneous nature of the graft, it has proven very useful to understand the histology of chlamydiae in actual fallopian tube tissue.

## Mouse Model

For the obvious reasons of lower cost and availability of a vast array of reagents and genetically manipulated animals, the mouse remains a very desirable animal to employ as a model for an infectious disease. Particularly with respect to the study of the host response, the mouse is by far the best model because of the available resources. With respect to chlamydial genital infections, female mice can be infected with *C. trachomatis* or the natural mouse chlamydia, *C. muridarum*. Both infections generally resolve in 3–4 weeks following intravaginal inoculation, considerably shorter than human infections. Furthermore, infection with *C. trachomatis* is mild and requires pretreatment of mice with Depo-Provera for infection to occur while *C. muridarum* can infect mice and produce a heavy infection in mice with or without Depo-Provera treatment, the hormone being primarily to stabilize

the estrous cycle of the mice in anestrus to facilitate infection, as mice cannot be infected during estrus.

Clearly, the advantage of infecting mice with *C. trachomatis* is that one is studying the actual human pathogen. Mice can be infected with all serovars of *C. trachomatis*; and interestingly, the course of the infection varies significantly based on the serovar used.<sup>21</sup> However, the major disadvantage of the model using human serovars is that pathology of the oviducts is very minimal following intravaginal inoculation, so the model's use is limited in the study of upper tract disease.<sup>22</sup>

*C. muridarum*, on the other hand, elicits a more aggressive infection and commonly causes ascending infection and long-term pathology in the oviduct, although the latter is dependent upon the strain of mouse used.<sup>22</sup> One can argue that *C. muridarum* is more relevant, particularly in the study of the host response because it is a natural parasite of the mouse. *C. muridarum*, the agent of mouse pneumonitis, was first isolated from the respiratory tract of mice<sup>23,24</sup> and was characterized as a model for genital infection by Barron and Rank.<sup>25,26</sup> There are two strains of *C. muridarum*, the Weiss strain and the Nigg strain. Both were isolated from mice at the University of Chicago, but a recent study has shown that they have distinct pathogenicity phenotypes with the Weiss strain being the more virulent of the two organisms.<sup>27</sup> The length of *C. muridarum* infection is also dependent upon the strain of mouse infected with C57 mice generally resolving the infection more quickly than Balb/c and C3H mice.<sup>22,28</sup> The pathologic response following chlamydial infection with *C. muridarum* has been well characterized in the mouse. Just as in the non-human primate, initially, there is a strong acute inflammatory response but within 7–10 days, a chronic inflammatory response consisting of CD4 and CD8 T cells and monocytes/macrophages appears which may persist at low levels for a period of time after the infection has resolved. The infection ascends the genital tract and causes scarring resulting in tubal obstruction and hydrosalpinx.

Virtually all of the studies on chlamydial genital infection in the mouse have been in the female; however, because the reproductive anatomy and physiology, especially with respect to the estrous cycle is completely different from the human, it probably is not the ideal model in which to study the pathologic response at the system level. Nevertheless, at the molecular and cellular level, the responses should be predicative for the human. Recently, infection of male mice has been demonstrated although this remains a difficult model because of the inability to monitor the infection sequentially in the same animal.<sup>29</sup>

## Guinea Pig Model

Analogous to the mouse, guinea pigs can be infected in the genital tract with a chlamydia native to guinea pigs. *Chlamydia caviae*, or the agent of guinea pig inclusion conjunctivitis, was originally isolated from the conjunctiva of young guinea pigs by Murray<sup>30</sup> and was found that it could also elicit a genital tract infection when inoculated intravaginally.<sup>31</sup> The infection resolves in 3–4

weeks, also shorter than human infections, and targets the exo- and endocervix but ascends the genital tract to the endometrium and oviducts in 80% of the animals.<sup>32</sup> The pathologic response, particularly in the oviducts is remarkably similar to the human. Just as in the non-human primate and the mouse, the initial host response is an acute inflammatory responses transitioning to a chronic inflammatory response, including CD4 and CD8 T cells, plasma cells, and monocytes/macrophages.<sup>32,33</sup> Of the animals that develop infection in the oviduct, only about 45% actually develop a pathologic response, but this may result in pyosalpinx followed by fibrosis, tubal obstruction, and hydrosalpinx.

An important advantage of the guinea pig is that the female has an estrous cycle of 17 days and very closely mimics the reproductive physiology and endocrinology of humans.<sup>34</sup> Infection in animals treated with estrogens and actual oral contraceptives is exacerbated with increased inflammation and incidence of upper tract disease<sup>35–37</sup>; thereby supporting studies in humans showing that women taking oral contraceptives have an increased incidence of chlamydial infection.<sup>38</sup>

Just as in humans, when pregnant guinea pigs are infected intravaginally, they are able to transmit the infection to the newborns at birth, resulting in inclusion conjunctivitis.<sup>31</sup> Unlike many other rodents, guinea pigs are fully haired and have their eyes open at birth. While it has not been demonstrated that newborn guinea pigs can develop pneumonitis at birth, typical chlamydial pneumonitis of the newborn has been produced by intranasal inoculation of 1 week old animals.<sup>39</sup> The pneumonitis is relatively mild but is very characteristic of chlamydial pneumonia in human neonates.

A major advantage of the guinea pig model is that male guinea pigs can be infected in the urethra and the course of infection can be monitored by urethral swabs.<sup>40,41</sup> Similar to the female guinea pig, the infection in the male resolves in about 3 weeks. The histopathology in the male urethra is also very similar to the female with an initial acute inflammatory response followed by a chronic inflammatory response. Ascending infection to the bladder has been documented in the immunologically intact animal, although it is uncommon. No evidence of infection of the seminal vesicles, prostate, vas deferens or epididymis has been found. However, if animals are immunosuppressed, a high incidence of cystitis can be observed as well as an occasional animal with organisms in the epididymis. Interestingly, both male and female guinea pigs can be infected intrarectally with the infection lasting 2–3 weeks.<sup>42</sup>

Perhaps the most significant aspect of the guinea pig model is that actual sexual transmission of chlamydiae from infected males to females can be reliably accomplished.<sup>43</sup> The females must be monitored to determine when they will enter estrous, and then males infected in the urethra are housed with the females about 6 days before the expected estrous. Infection of the female occurs in about 70% of the matings. It was particularly interesting that the course of cervical infection in the female inoculated sexually is significantly shorter than animals artificially infected with a comparable dose. It is tempting to speculate that chemokines

and cytokines in the semen may accelerate the host response in the female.

## HOST RESPONSE

Infection of each of the animal models generates a strong immune response and the animals develop immunity to reinfection, although the degree of immunity is dependent upon when after resolution of the infection the animals are challenged. In both the mouse and guinea pig, when challenged within 1 month after resolution of the infection, animals exhibit complete immunity, i.e., the animals do not become reinfected. However, when animals are challenged after a longer period of time, they do become reinfected, albeit the infection level is reduced and the course of the infection is abbreviated. When male and female guinea pigs infected with *C. caviae* were compared, the males maintained complete immunity for a longer period of time than did the females.

Vast majority of the immunologic studies have been performed in the mouse and guinea pig models. Each develops a substantial antibody response in both serum and genital secretions, with IgG dominating in both sites, although IgA is also elicited in the genital tract.<sup>45,46</sup> The IgG antibody develops concomitant with the resolution of the infection and remains at high titers for long periods of time in both serum and secretions, while IgA in secretions dissipates in about 50 days. The humoral immune response appears to be essential for both resolution of and resistance to infection in the guinea pig model<sup>47,48</sup>; however, antibody appears to be only important in immunity to challenge infection in the mouse.<sup>49</sup> It is not clear in humans how critical humoral immunity is.

In contrast to the humoral response, cell-mediated immunity is essential for both resolution of and resistance to chlamydial genital infection in both animal models.<sup>50</sup> Protective immunity associated with cell-mediated immunity is dependent upon a CD4 Th1 response which is consistent with data accrued in human studies.<sup>51,52</sup> While CD4 cells are essential for immunity to chlamydial genital infections, CD8 cells, although present, are not essential for immunity. The short-term nature of complete immunity appears to be dependent upon the presence of T cells in the genital tract.<sup>53</sup> Upon resolution of infection, T cells no longer localize in the genital tract, and animals again become susceptible to reinfection, albeit reinfection is shorter in duration and less intense.

## SUMMARY

There are three primary animal models used by researchers in the field of chlamydial research. While the non-human primate most closely resembles human disease, its use is limited by cost and availability. *C. trachomatis* is able to infect mice in the genital tract but the infection is generally relatively mild and the development of oviduct pathology is uncommon. The two best models for chlamydial genital infections, the mouse and guinea pig, employ agents which are host-specific and natural parasites

of each animal. The mouse infected with *C. muridarum* is ideal for the study of immune and pathologic mechanisms, while the pathogenesis and pathology associated with *C. caviae* infections appear to be more closely related to the human disease. Both can be used to evaluate potential vaccine candidates but primarily as proof-of-principle since *C. muridarum* and *C. caviae* only share genus-specific determinants with *C. trachomatis*. Infecting the mouse with *C. trachomatis* does provide the potential to test a human vaccine, but again, does not have the more severe pathologic sequelae of *C. muridarum*. Sexual transmission can only be accomplished in the guinea pig because of its similarity to humans in reproductive endocrinology.

## Gonorrhea

The development of an animal model to mimic human genital infection with *Neisseria gonorrhoeae* has been a difficult target, primarily because of the organism's unique specificity for the human host and the total lack of natural *Neisseria* species for rodents. In particular, the CD46 receptor required for pili-mediated attachment<sup>54</sup> and carcinoembryonic antigen<sup>55</sup> utilized for attachment by *Opa* proteins are not present in mice, nor can human transferrin or lactoferrin be utilized as sources of iron.<sup>56</sup> To some extent the lack of an optimal animal model has been compensated by the actual experimental inoculation of the urethra in human males.<sup>57</sup> While these experiments have yielded a significant amount of data, especially with respect to evaluating different mutant organisms and vaccine candidates, for obvious reasons, the entire course of infection, basic mechanisms of pathogenesis, and the host response cannot be studied in sufficient detail. Moreover, because of the potential for upper tract infection, female subjects cannot be studied so one cannot investigate factors specific to the female reproductive tract. A number of different animals have been tested for susceptibility to gonococcal infection<sup>58</sup> but only the non-human primate and mouse will be discussed below.

### DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

#### Non-Human Primate

The only animal model in which urethral infection with gonococci could be induced, lasting 3–6 weeks, similar to humans, is the chimpanzee (*Pan troglodytes*). Male chimpanzees were inoculated in the urethra with either exudate from infected human males or approximately  $4 \times 10^7$  colony-forming units (CFU) of gonococci maintained by *in vitro* passage, contained in 2 ml of broth culture and the course of infection monitored by urethral swab.<sup>59,60</sup> Organisms could be detected from urethral swabs as early as 3 days after inoculation and were still detected 49 days after infection, after which the infection resolved. Clinical signs of urethritis, i.e., a slight discharge, were observed between 10 and 15 days after inoculation with *in vitro* cultured bacteria but in animals inoculated with exudate, the discharge lasted from days 4

to 30 and was quite prominent in the second week of infection. An exciting part of this model is the ability of *N. gonorrhoeae* to be transmitted from males to females.<sup>60</sup> The infected male chimpanzee was housed with a female and culture evidence of infection of the female by endocervical swab was obtained within 5 days. Organisms could be recovered as long as 39 days after exposure. There were no obvious clinical signs of infection in the female. While the chimpanzee would appear to be an excellent model for gonococcal infection, it is impractical to use because of expense and a limited supply of animals.

#### Mouse Model

There have been multiple attempts to produce a mouse model for genital infection with *N. gonorrhoeae*,<sup>61</sup> but until relatively recently, the results have been unsatisfactory. In general, in most attempts to model gonococcal genital infection in mice, the infections have been short-term and restricted to inoculation of mice during proestrous. Kita and colleagues were able to elicit a longer term infection in a particular strain of mice with endometrial cultures being positive for about 1 month<sup>62</sup>; however, these data were not able to be repeated in another laboratory using the same mouse strain.<sup>61</sup>

Because of the apparent restriction on susceptibility of infection to proestrous in mice, when estrogen levels are increasing as well as an apparent inhibitory effect of normal vaginal flora, Taylor-Robinson injected germ-free mice with 17- $\beta$ -estradiol prior to inoculation with  $2 \times 10^6$  gonococci.<sup>63</sup> As a result, they were able to culture gonococci from the vagina for up to 39 days. Organisms could also be detected in the endometrium and ovary. Nevertheless, no inflammation was observed.

In a modification of the model presented by Taylor-Robinson, Jerse inserted a 5 mg, 21 day controlled release pellet intradermally into Balb/c mice in the diestrous stage of their cycle, and at the same time, injected mice with an antibiotic cocktail consisting of streptomycin sulfate and vancomycin and added trimethoprim sulfate to their drinking water to reduce the normal vaginal flora.<sup>61</sup> Two days later, mice were inoculated intravaginally with *N. gonorrhoeae*. She evaluated inoculation with  $10^5$ – $4 \times 10^6$  CFU of three different strains. The length of the resulting infections varied according to the strain of gonococcus and the size of the inoculating dose, but ranged overall from 4.8 to 13.6 days. The infection course was generally over 12 days when  $10^6$  or more CFU were inoculated. The number of bacteria cultured from the vagina also varied greatly, ranging at peak levels from  $10^3$  to about  $4 \times 10^6$  CFU. Significantly, in this model, an acute inflammatory response could be detected in the vagina of the majority of infected mice, clearly indicating a pathologic response to the infection analogous to humans. It is also noteworthy that diplococci could be found associated with and within neutrophils, just as is classically observed in exudates from humans.

The regimen was later modified to use a water-soluble estradiol instead of the slow release pellet.<sup>64</sup> Similar results were observed in that the mice became infected, there was an infiltration of

PMNs, and the infection resolved concomitant to the loss of the estradiol effect.

Certainly, in humans gonococci may ascend the female genital tract and cause endometritis, salpingitis, and pelvic inflammatory disease (PID). When Jerse cultured endometrial tissue of animals infected intravaginally with *N. gonorrhoeae*, she did indeed isolate organisms but only in a low percentage of mice (17–20%) with a given strain of bacteria. No infection in the oviduct was reported. Nevertheless, the model does have the potential to model upper genital tract infection with gonococci.

Perhaps the most valuable aspect of this model is the ability to study the effect of the *in vivo* milieu on the genetic variation so characteristic of *N. gonorrhoeae*. While 99% of the organisms from two different strains were found to be piliated in culture, upon isolation from the mouse vagina with 48 hours of inoculation, the majority of the organisms had no pili, indicating that perhaps pili were not necessary for attachment in the mouse.<sup>61</sup> In contrast, the *Opa* protein, an important attachment protein with a high level of antigenic variation, is expressed on gonococci in the mouse genital tract. In fact, when mice were inoculated with a predominantly *Opa*-negative population, a high percentage of the isolates of several mice 14 days after infection were *Opa*-positive while the inoculum, passed for 5 days on artificial medium, did not express the *Opa* protein. These results paralleled observations in humans when *Opa*-negative organisms were inoculated in the male urethra and subsequent isolates were *Opa*-positive.<sup>65</sup> Similarly, just as in the human male model, isolates from individual mice did not necessarily express the same *Opa* protein, indicating a selection process in the mouse vagina. Selection for *Opa* proteins occurs in the mouse model in the absence of human carcinoembryonic antigen adhesion molecules, the major adhesion receptor for the *Opa* protein, and the recovery of *Opa*-positive variants from female mice is cyclical over time, which suggests the influence of reproductive hormones on *Opa* phenotype.<sup>66</sup> Overall, this model has proven to be valuable in examining basic host/bacteria interactions, including alternative mechanisms by which gonococci obtain iron in the mouse in the absence of transferring,<sup>67</sup> mechanisms by which gonococci resist killing by PMNs,<sup>68,69</sup> the role of lactate in *in vivo* survival,<sup>70</sup> and the evaluation of topical microbicides.<sup>71</sup>

## HOST RESPONSE

It is quite obvious in humans that a strong innate host response develops, but there is little evidence for the development of a protective immune response, as individuals can be infected multiple times. The host response to gonococcal infections has proven difficult to study because of the lack of a convenient model that truly mimics human infection. There is no doubt that an active innate response in the mouse develops upon infection, mainly as a result of the observed PMN influx to the local site. However, even though the infection in the mouse resolves, it is more likely that the resolution is dependent upon the loss of serum estradiol rather than the development of a protective

immune response.<sup>64</sup> When mice having recovered from a genital infection were reinoculated with the same strain, no difference was noted in the course of the infection from age-matched mice given a primary infection, supporting observations in humans.<sup>64</sup> It was also interesting in that there was only a transient IgG and IgA antibody response in vaginal washings and sera. Challenge infection did not show any evidence for an anamnestic antibody response. Therefore, there does not appear to be any substantial or sustained immune response to gonococcal infection in the mouse genital tract. While this may seem disappointing, the model, nevertheless, is reflective of the human situation.

That the mouse model can be used to evaluate potential vaccine candidates was demonstrated by Plante and colleagues.<sup>72</sup> They immunized mice intranasally with outer membrane preparations and then challenged the mice intravaginally. A reduction in the length of infection for the immunized mice indicated that a protective response had been elicited by the immunization regimen. An antibody response to several gonococcal antigens was observed in both serum and secretions.

## SUMMARY

The search for an instructive animal model for gonorrhea has been a difficult task, to a great extent, because of the unique specificity of the organism for its human host. While the chimpanzee appears to double for the human with respect to the specificity, there are the usual problems of expense and availability. The mouse model developed by Jerse is not perfect as well but does display many of the characteristics of human disease, i.e., development of an acute inflammatory response and lack of protective immunity or even a substantial adaptive immune response. Perhaps this model is best exploited to investigate mechanisms by which the organism evades or survives in the presence of an inflammatory response, mechanisms of antigenic variation, physiologic requirements of the organism *in vivo*, and the impact on the organism by the host physiology, which are areas already under investigation.

## Mycoplasma Genitalium Infection

*Mycoplasma genitalium* is a recently recognized sexually transmitted pathogen, first identified as a likely cause of inflammatory urogenital disease in men.<sup>73–75</sup> In the two decades since identification, *M. genitalium* has been implicated in several important female reproductive tract syndromes including endometritis, PID, cervicitis, and serologically with salpingitis and impaired fertility.<sup>76–80</sup> In men, *M. genitalium* is associated with non-gonococcal urethritis (NGU).<sup>75,81–84</sup> Overall, the data support but do not prove a causal role for ascending *M. genitalium* infections and the observed clinical outcomes.

Animal modeling of *M. genitalium* infections should help establish the causal relationships with both genital tract and joint infections as well as provide a means of testing novel vaccines and interventions. Unfortunately, the development of animal models has been hampered by the extremely fastidious nature of *M. genitalium* that makes confirmatory culture from human

and animal samples difficult.<sup>74,85–87</sup> For this reason, detection methods for *M. genitalium* are shifting to PCR quantification of the bacterial genome for diagnostic and research purposes. Using these enhanced detection methods and the successful modeling of other genital bacterial infections described in other sections of this chapter, several animal models for *M. genitalium* have been developed. Specifically, *M. genitalium* genital tract colonization has been achieved in non-human primate species and in hormonally conditioned mice as reviewed in several reports.<sup>88,89</sup> Finally, several genetically related *Mycoplasma* spp. have been used as surrogates of *M. genitalium* infection with successful genital tract infection of selected animal species.<sup>89–95</sup>

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Non-Human Primates

As is the case for several other sexually transmitted pathogens, successful modeling of some of the aspects of *M. genitalium* infection has been achieved in both genders of selected non-human primates. Prior to experimentation, vaginal and urethral samples from each of the non-human primate species showed no evidence of natural infection by *M. genitalium*. Experimental infections of both male and female non-human primates were attempted by urethral or intravaginal application and in a subset of females by intraoviduct or transcervical administration of *M. genitalium*. The data are limited due to the associated costs and limits on available subjects for these species but collectively indicate that these species support varying levels of persistent colonization by *M. genitalium*, but they experienced minimal pathology. The pathologies that were observed model the inflammatory nature of this infection and suggest that *M. genitalium* likely contributes to infertility.

In the initial sets of studies, Taylor–Robinson and colleagues inoculated the urethra of male chimpanzees (*Pan troglodytes*)<sup>96</sup> with a culture adapted *M. genitalium* strain designated G-37 that was isolated from a male with a case of non-gonococcal urethritis.<sup>97</sup> In this first study, 4 young male chimpanzees were inoculated via the urethra and monitored for persistent colonization. Despite concerns regarding the clearing effects of urination, two of the animals developed infections as evidenced by persistent recovery of organisms from urethral swabs over 13 weeks of monitoring. A G-37 derivative was isolated from one of the animal's urethral samples and was used as a chimpanzee-adapted strain for subsequent studies. Subsequent animals were persistently colonized including at least 2 animals that were found to have blood-borne *M. genitalium* suggesting that systemic infections were possible.<sup>98</sup> Taylor–Robinson and colleagues also experimentally inoculated Rhesus macaques (*Macaca mulatta*) and found them to be “insusceptible.”<sup>88</sup> Cynomolgous monkeys (*Macaca fascicularis*) were found to be susceptible with 4 of 6 inoculated animals showing signs of colonization albeit with low levels of recovered organism in 2 animals.<sup>88</sup> In the other 2 animals

high numbers of organism ( $<10^7$  color-changing units (CCU)/mL) were isolated from urethral samples for up to 28 days.

Experimental infection of female animals also was evaluated in a number of non-human primate species. Specifically, female squirrel monkeys (*Saimiri sciureus*), tamarins (*Saguinus mystar*) marmosets (*Callithrix jacchus*), baboons (*Papio anubis*), and chimpanzees were colonized to some degree by *M. genitalium* following high titer inoculation.<sup>88</sup> Of the female non-human primates, vaginal inoculation of marmosets led to prolonged infection and inflammation of the genital tract. In an initial study, 6 female marmosets were inoculated vaginally with the G37 type strain and were followed for persistent infection and host response outcomes.<sup>97</sup> Vaginal swabs indicated 4/6 animals were actively infected and that *M. genitalium* persisted in the lower genital tract for up to 149 days similar to clinical case reports. Importantly, the 2 inoculated but uninfected animals and 2 mock-inoculated controls included in the study provided baselines for comparison to identify host responses and pathologies engendered by *M. genitalium*.

Female tamarins, squirrel monkeys, and chimpanzees also proved susceptible to colonization by *M. genitalium* following vaginal inoculation with high-titer stocks of the G37 type strain.<sup>88,98</sup> The authors concluded that these animals were colonized, albeit at low levels, using culture of vaginal swab specimens in specialized SP4 growth medium.<sup>75</sup> The fastidious nature of *M. genitalium*, the difficulties of axenic outgrowth from swab samples, and the use of PCR indicating high genomic burden in otherwise culture-negative samples likely indicates that these animals supported a more substantial level of infection than indicated by the SP4 outgrowth. Studies using PCR as an outcome measure have not been published.

Another aspect of clinical *M. genitalium* infection is ascension and damage to the upper reproductive tract. Of the non-human primates tested, squirrel monkeys and chimps both showed inflammatory outcomes in the lower genital tract but provided no evidence of natural ascension to the upper tract.<sup>88,98</sup> Intraoviduct administration is a commonly employed methodology to model infection of the upper tract when vaginal inoculation fails to create a natural ascension of the pathogen predicted by clinical observations. In a study designed to model upper tract infection, 3 female marmosets received G37 via intraoviduct inoculation during a laparotomy that produced endosalpingitis and lower genital tract colonization.<sup>88,99</sup> Intraoviduct inoculation also was performed in 2 grivet monkeys (*Cercopithecus aethiops*) where, like marmosets, salpingitis was produced but, in this case, no obvious lower tract colonization was observed. Of the non-human primates tested, squirrel monkeys and chimps both showed inflammatory outcomes in the lower genital tract but provided no evidence of ascension to the upper tract or the more serious pathologies.<sup>88,99</sup> Finally, to better model natural infection, 3 female baboons (*Papio anubis*) were inoculated with *M. genitalium* across the cervix and followed for lower tract colonization and upper tract disease. Two of the 3 animals had persistent vaginal colonization and two developed pelvic inflammation.<sup>88</sup>

Collectively, the studies in non-human primates established that *M. genitalium* was capable of infecting lower and upper genital tract tissues but the extreme costs associated with development and maintenance of the primate animal models prohibited larger scale studies to address biological variability as part of an effective model of reproductive tract infection.

## Mouse Model

Smaller animal models have been evaluated over the last two decades to address the non-human primate short-comings and to provide opportunities to evaluate therapies and interventions including novel vaccines and antibiotics. Although other small animals were evaluated, mice seem to offer the greatest potential. Initial experiments by Furr and Taylor–Robinson provided evidence that *M. genitalium*, strain G-37, could establish experimental genital tract infections in female mice,<sup>95</sup> but, to date, no evidence of infection of male mice has been published. There are several closely related *Mycoplasma* spp. that have been used as surrogates for modeling of *M. genitalium* genital tract infection, including *M. pneumoniae*, *M. pulmonis*, and *M. fermentans*. In fact, in a single reported male mouse study with *M. pulmonis*, an interesting phenomenon was observed in many of the inoculated animals in three of six tested inbred lines of mice.<sup>100</sup> At periods of time distant from inoculation, inoculated male mice experienced prolonged priapism that lasted in one case 44 weeks. In fact the authors noted “erections that persisted, apparently continuously, for up to 44 weeks can certainly be described as priapism, although so remarkable is the phenomenon in duration that it would seem to deserve a different term to reflect this aspect.”<sup>100</sup> This condition has anecdotal correlates in clinical literature and may be related to hypercoagulation associated with *M. pneumoniae* infection.<sup>101</sup>

For female animals, experimental infection by *M. pneumoniae*, *M. pulmonis*, and *M. fermentans* required hormonal conditioning to enhance susceptibility to infections.<sup>88,92,95,102</sup> Synchronization of the estrous cycle offered additional advantages for subsequent evaluations including pathology development and fertility issues. Importantly, by increasing susceptibility, hormonal conditioning reduced the numbers of animals required per group. Capitalizing on the successful modeling of other STI pathogens, including those detailed in this chapter, and using related *Mycoplasma* spp. as surrogates, Taylor–Robinson and colleagues tested the susceptibility of hormonally conditioned inbred mice to *M. genitalium* infection. Their preliminary studies showed that progesterone conditioned but not estradiol benzoate-treated BALB/c mice were susceptible to vaginal *M. genitalium* infection.<sup>88</sup> This was consistent with susceptibility to the surrogates *M. pneumoniae* and *M. pulmonis* but was distinct from estrogen-based susceptibility to the genital pathogen, *M. fermentans*, that only colonized estrogen-conditioned mice.<sup>95,102</sup> Unfortunately, there was no evidence of ascended infection or upper tract pathology in the progesterone-conditioned animals.<sup>88,95</sup>

In the decades following these initial studies, the quality and formulations of both progesterone and estradiol were improved

and now include long-acting versions that are utilized for a number of STI animal models. Utilizing longer acting Depo formulations of both progesterone and estrogen, a recent set of studies showed a differential infection pattern but indicated both conditions allowed for persistent vaginal colonization.<sup>103</sup> For these studies, several inbred lines and the commonly used, outbred Swiss Webster mice were found to be susceptible following two injections of either estradiol cypionate (0.25 mg; Depo-estradiol, Pfizer) or medroxyprogesterone acetate (3 mg; Sicor, CA) at 7 and 1 day prior to *M. genitalium* inoculation. A high-titer inoculation ( $2 \times 10^7$  CCU) was vaginally delivered for the G-37 type strain and a low passage, contemporary isolate designated M2300<sup>104</sup> after extensive washing and resuspension in sterile PBS. After this inoculation, *M. genitalium* reproducibly colonized both the lower and upper reproductive tract tissues persistently. Infected animals shed viable organisms from the vaginal cavity for several months with vaginal titers maintained at low levels (average of  $5 \times 10^4$  genomes/swab). These more recent studies also utilized PCR-based assays<sup>87</sup> to evaluate tissues and swabs from inoculated animals. Vaginal shedding was intermittent with an average of 50% of the collected swabs being PCR-positive at each sampling time.<sup>103</sup>

Using the more sensitive PCR-detection approach, it was possible to identify preferred sites of colonization in the upper tract of the mouse as a predictor of the sites infected in humans. Based on both PCR and viable organism outgrowth, an interesting outcome of the two tested hormonal conditions was the differential ascension of the infection into the upper tract and possibly systemic dissemination of the bacteria.<sup>103</sup> Animals conditioned with estradiol cypionate were more often found to have upper tract colonization and had a higher frequency of hydrosalpinx development.<sup>103</sup> Specifically, estrogen-dominated animals infected with either G-37 or M2300 had detectable *M. genitalium* in the uterine horns at 3 days host infection, in the oviducts by 7 days post-infection and in knees on day 10 post infection. Such data suggest a causal role for *M. genitalium* in cases of infertility. Interestingly, by PCR, *M. genitalium* also was detected in the knee joints of infected mice providing evidence that *M. genitalium* may disseminate from the vagina to colonize synovial sites offering a potential model of reactive arthritis. Finally, the hormone-dependent susceptibility to *M. genitalium* is compatible with other bacterial STI models allowing for the potential to model co-infections as described later in the chapter.

## HOST RESPONSE

Human infection leads to a directed antibody response<sup>74,105–107</sup> but there is little to no information regarding cell-mediated immunity at present. In females a pronounced antibody response to the major adhesin protein, MgPa, has shown<sup>105,108,109</sup> some cross-reactivity with other *Mycoplasma* spp.<sup>107</sup> Clinically, the associated conditions suggest there is a strong inflammatory component to the host response that has been modeled in human cell cultures<sup>110,111</sup> and is beginning to be evaluated in animal models.

Male non-human primates that were infected via the urethra, showed a transient urethral response that included increased numbers of polymorphonuclear leukocytes that was absent after the animals were treated successfully with antibiotics.<sup>96</sup> The infected animals also showed significant increases in serum antibody to *M. genitalium* proteins. One of two chimpanzees with resolved infection was challenged 6 months after antibiotic treatment but was not infected suggesting that it was immunologically protected.<sup>96</sup> Female chimpanzees also developed increased numbers of polymorphonuclear leukocytes in vaginal samples following infection with subsequent increases in antibody titers to *M. genitalium*.<sup>88</sup> In subsequent studies with infected chimpanzee sera, Morrison–Plummer and colleagues showed that a selected set of immunodominant epitopes were common to the chimp antibodies and to infected humans.<sup>107</sup>

Studies in the mouse suggest similar host responses to those reported in humans and in the limited primate studies. The lower cost and availability of mice allowed for several studies to be completed to address potential cross protection by respiratory infection with *M. pneumoniae* to subsequent vaginal infection by *M. genitalium*.<sup>112</sup> These studies showed that respiratory infection by *M. pneumoniae* protected mice against vaginal challenge with the same organism<sup>95</sup> but not against vaginal challenge with *M. genitalium*.<sup>112</sup> In more recent studies, infected mouse sera were tested on lysates of *M. genitalium* by immunoblot.<sup>103</sup> Proteins bound by the mouse antibodies were then characterized by MALDI-TOF/TOF mass spectrometry confirming that MgPa also was observed to be an immunodominant protein in outbred mice. Additional proteins recognized by the mouse sera included *M. genitalium* EF-Tu, DnaK (Hsp70) and the E1  $\alpha$  subunit of pyruvate dehydrogenase.<sup>103</sup> Interestingly, each of these proteins is considered a putative component of the cytoskeleton in *M. pneumoniae*<sup>46</sup> suggesting that they should be evaluated for function in *M. genitalium* replication, human infection and as novel targets for clinical diagnostics.

Finally, the mouse has provided some insights into the initial responses to infection that may be chronically elicited contributing to the clinical pathologies associated with *M. genitalium* infections.<sup>113</sup> In recent studies, human genital tract and macrophage cell cultures elicited proinflammatory responses when they were exposed to live or dead *M. genitalium* or fractionated or recombinant *M. genitalium* proteins.<sup>110</sup> The utility of the mouse model should allow a systematic evaluation of the cytokines and chemokines elaborated from infected vaginae as well as cell-mediated immune responses in genital and possibly joint tissues. Importantly, direct, causal associations with inflammatory disease and its impact on fertility could be explored in the mouse model.

## SUMMARY

The recent identification of *M. genitalium* as a genital tract pathogen that is transmitted sexually has created an active field of research that includes the creation of useful animal models. The research has been aided by the success with other STI pathogen modeling as well as success with closely related *Mycoplasma* spp. Unlike other bacterial

STI with similarly narrow host range, the non-human primate studies suggest that *M. genitalium* may not create the same pathologies in female animals reducing the utility of these extremely costly and limited species. Early success with mouse modeling led to recent interest and improvements utilizing different formulations of both estrogen and progesterone. The resulting mouse vaginal challenge model that showed several inbred lines, including C57Bl/6 and a common outbred mouse strain were susceptible to persistent colonization and upper tract infection should allow future studies of vaccines and interventions. The limited host response data suggest that mouse and man have similar immunodominance hierarchies. The mouse also offers an opportunity to address basic pathology questions including the role of *M. genitalium* in fertility. Finally, because mice could be made susceptible to infection following either estrogen or progesterone conditioning, co-infections with other STIs may be modeled in the mouse.

## Syphilis

Of all the sexually transmitted infections, research on syphilis has probably been carried out for the longest period of time. *Treponema pallidum* has been an exceptionally difficult organism to work with because of the simple reason that it cannot be cultured *in vitro* and requires inoculation into rabbit testes for production of sufficient organisms for experimentation. Unlike chlamydial and gonorrheal infections which gain access to the lumen of genital tract via fluid transfer, *T. pallidum* enters the body via microabrasions of the skin or mucosal epithelium leading to local replication and subsequent dissemination to the draining lymph nodes and peripheral circulation, so that the resulting disease is systemic rather than a local mucosal infection. Thus, in modeling syphilis, it is not critical that infection be initiated in the reproductive tract of males or females, but rather it should be able to demonstrate local dermal infection followed by systemic spread. Initially, there was a great deal of difficulty in producing an effective animal model until it was recognized that the key factors in infecting animals were the strain of *Treponema* used and the size of the inoculating dose, generally at least 10<sup>7</sup> organisms.<sup>114</sup> Virtually, all of the animal studies since the 1950s have utilized the Nichols strain, originally isolated from human cerebrospinal fluid (CSF) in 1912.<sup>115</sup> The primary model used for syphilis research is the rabbit although the guinea pig has also proven to be an useful model. For a brief period, some studies were initiated with the Syrian hamster but this model has not been used in recent years.<sup>116</sup> Some studies have also been published using non-human primates.<sup>117</sup> The early studies on animal models for syphilis are extensively reviewed by Turner and Hollander.<sup>114</sup>

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Rabbit Model

The most commonly used and arguably an indispensable animal for research on syphilis is the rabbit because of the necessity to

grow *T. pallidum* in rabbit testes to produce organisms for all aspects of treponemal research. Generally, New Zealand white rabbits are used, although care must be taken to determine if there is any serologic evidence for infection with *Treponema paraluis-cuniculi*, a naturally occurring treponemal infection of rabbits.<sup>118</sup> Male rabbits are routinely injected in each testicle with 1 mL of  $2\text{--}4 \times 10^7$  spirochetes. In 7–11 days after orchitis has developed, animals are euthanized and the organisms are extracted from the testes.<sup>119</sup> Yields can be increased by injections of cortisone acetate following infection.

In order to characterize the pathogenesis of testicular infection, male rabbits were injected with  $2\text{--}10 \times 10^7$  organisms in each testicle and were euthanized at various times after infection to evaluate the early stage of infection.<sup>120</sup> Inflammation of the testes was apparent by 6–8 days after infection and the testes were enlarged and somewhat hemorrhagic. The peak level of orchitis occurred between 8 and 13 days after infection, doubling in size with diffuse swelling and firmness, and then returning to normal size by 31 days after infection. Microscopically, there was an obvious interstitial lymphocytic infiltration by day 6, increasing to peak levels by days 10–13 with the majority of the cells identified as T cells and only a few B cells. Subsequently, the cellular content began to decrease with an increase in interstitial fibrosis and apparent cure. Treponemes were first detected by fluorescent-labeled antibodies at day 3 and continued to multiply through day 13. The number of organisms decreased dramatically following the peak T-cell response and could not be detected by immunofluorescence by day 17 and thereafter. Nevertheless, while there appears to be local resolution of the infection, organisms may persist in the lymph nodes and perhaps blood for 3–4 years in a period of latency.<sup>114</sup>

Similar to testicular injection, inoculation of  $2 \times 10^7$  spirochetes intradermally results initially in erythema and induration at the site of infection by days 3–4, reaching maximum size of 16 mm by 2 weeks after infection.<sup>121</sup> Central ulceration then develops with resolution of the lesion by day 36. In this particular study, spirochetes could be detected up to 2 weeks after infection but disappeared by 4 weeks. However, at 6 weeks, organisms could be found in the testes, spleen, and lymph nodes, indicating systemic dissemination. Earlier studies demonstrated that *T. pallidum* rapidly disseminates systemically and persists for the lifetime of the animal.<sup>114</sup> The histopathologic response in the dermis was also similar to the response in the testes. Initially, a slight perivascular and diffuse infiltration of the dermis and subepidermal tissues with mononuclear cells developed, the majority of which were T cells. The mononuclear inflammatory response continued to increase by 2 weeks with extensive lymphocytic infiltration surrounding the hair follicles, and then declined by 4 weeks, concomitant with the disappearance of organisms. Thus, the dermal response to *T. pallidum* in the rabbit is remarkably similar to the primary lesion in human syphilis.

Obviously, syphilis is a complex disease with pathologic considerations extending beyond the dermis and early stage disease. One of the major aspects of late syphilis is the invasion

of the CSF and the development of neurosyphilis. Marra and colleagues were able to use the rabbit to model early infection of the central nervous system.<sup>122</sup> Rabbits were inoculated intracisternally with  $1.5\text{--}5.1 \times 10^7$  spirochetes. Serologic evidence (VDRL) for infection was in 86% of the animals by 2 weeks and in all animals by 4 weeks after inoculation. When the CSF was evaluated, mononuclear pleocytosis could be seen by 2 weeks after infection, increasing to peak levels by 9 weeks and persisting as long as 20 weeks; however, the response was not consistent with 50% of the animals having  $>10$  white blood cells/ $\mu\text{L}$  at 6 and 9 weeks after inoculation. Similarly, viable treponemes could only be demonstrated in the CSF and/or brains of 66% of the animals at 6 weeks after infection, but the presence of organisms did correlate with the peak mean serum VDRL titer and CSF pleocytosis.

Another key aspect of syphilitic disease is the transplacental transfer of organisms to the fetus, resulting in congenital syphilis. In order to model congenital syphilis, Fitzgerald inoculated pregnant animals intravenously at various times of gestation with varying doses of bacteria ranging from  $4 \times 10^8\text{--}4 \times 10^9$ .<sup>123</sup> In contrast to rabbits inoculated with killed organisms which had an 8% rate of stillborn, infected does had a 28–42% rate of stillborn offspring. Interestingly, only one of the offspring showed evidence for birth defects, and there did not appear to be any long-term developmental effects on the surviving animals. As evidence that organisms did indeed pass the placental barrier, viable organisms were indeed detected in extracts from fetuses from an interrupted pregnancy. Moreover, organisms were detected in the spleen of an offspring one week after birth.

## Guinea Pig Model

While not as susceptible to infection with *T. pallidum* as the rabbit, the guinea pig, nevertheless, has been used as a model for syphilis and can be infected intradermally, subcutaneously or intratesticularly with the intradermal route being the most effective and appropriate to model the disease.<sup>124</sup> Just as in the rabbit, the Nichols strain of *T. pallidum* is the most effective strain at eliciting disease, and the size of the inoculating dose is also critical in establishing infection. In addition, male guinea pigs and younger guinea pigs appear to be more susceptible to infection.<sup>124</sup>

When injected in the testes, guinea pigs do not develop orchitis to the same degree as rabbits, although spirochetes could be isolated from the testes and inguinal lymph nodes up to 6 months after infection. Intradermal inoculation produces lesions similar to the rabbit with an initial erythematous area 1–2 weeks after inoculation, progressing from a small papule to definite induration, finally becoming necrotic with ulceration.<sup>124–</sup>

<sup>126</sup> Organisms can be demonstrated by dark field examination in the lesions. In about 10% of the animals in one study, secondary lesions developed several weeks after resolution of the primary lesion.<sup>126</sup> Systemic spread and long-term persistence of the organism in the spleen and various lymph nodes was observed, just as in the rabbit.

Upon histopathologic examination of dermal lesions, a marked lymphocytic, histiocytic, and PMN infiltration was elicited and numerous treponemes could be detected.<sup>124</sup> In the lymph nodes, hyperplastic and hypertrophic changes in the germinal centers were observed reaching a maximum 6 weeks after infection but still apparent 18 months after infection.<sup>125</sup>

## HOST RESPONSE

In both rabbit and guinea pig models of syphilis, the lack of immunologic reagents has inhibited the detailed description of the host response that one can obtain in mouse models. However, with newer molecular techniques and the availability of rabbit and guinea genome sequences, the ability to assess a wider range of immunological parameters is becoming available.

The host response in both animal models, particularly in the rabbit, bears a great deal of resemblance to the human. In rabbits, there is no doubt but that a strong immune response develops following testicular infection resulting in resolution of the local infection even though organisms continue to persist in lymph nodes in a latent infection.<sup>120</sup> Evidence for immunity to intradermal infection challenge was apparent as early as 25 days after infection and was still present 73–80 days after infection.<sup>120</sup> In guinea pigs as well, the infection resolves but lymph nodes remain positive for as long as 6 months.<sup>124</sup> It is still not clear how the organism can persist in the lymphoid tissue in the presence of such an active immune response. Both rabbits and guinea pigs respond with both humoral and cell-mediated responses. Both produce antibody detectable by the FTA-ABS assay, but interestingly, antibodies to the cardiolipin antigen as measured by the VDRL or RPR assays, which develop in humans and rabbits<sup>127</sup> are not elicited in the guinea pig.<sup>126,128</sup> The presence of a profound T cell and mononuclear response is apparent upon histopathologic examination and is likely the key disease-causing mechanism.<sup>121,129</sup>

The appearance of T cells at the local site corresponds with the disappearance of treponemes from the lesion, suggesting that the cell-mediated immune response may be playing a role in the resolution of infection.<sup>129</sup> Analysis of the proliferative response of rabbit T cells to treponemal antigens was quite pronounced as well.<sup>119</sup> When the cellular constituency of the lesions was assessed by flow cytometry, the initial response shows a preponderance of CD4 T cells but CD8 T cells gradually entered the site as well.<sup>130</sup> Not surprisingly, the response was characterized as a Th1 response. Unfortunately, it has not been possible in the rabbit to establish the exact role of cell-mediated immunity in the protective response. However, adoptive transfer studies were performed in the guinea pig model. Pavia and Niederbuhl transferred immune splenic and lymph node cells into guinea pigs and then challenged the animals intradermally.<sup>131</sup> The resulting lesions in animals receiving immune cells were smaller in diameter and resolved more quickly than in guinea pigs receiving normal cells, and the numbers of treponemes in the lymph nodes were reduced. T-cell-enriched cells also demonstrated a protective response as did a B-cell-enriched population but to a somewhat lesser extent.

Interestingly, the passive transfer of immune serum to rabbits was also able to delay the development of lesions and reduce the lesion size.<sup>132,133</sup> In guinea pigs, the transfer of antibody reduced the number of animals developing lesions, as well as the number of organisms in the lymph nodes.<sup>134</sup> Thus, the data would suggest protective roles for both antibody and cell-mediated immunity, although clearly more work needs to be done to establish the exact mechanisms.

## SUMMARY

Clearly, the rabbit has been a valuable model for the study of syphilis and is able to model different aspects of the disease. Aside from the current lack of immunologic reagents, research with this model is impeded by the lack of inbred rabbit strains. Importantly, the reliance of the model on a single strain of *T. pallidum* makes it difficult to determine the impact of different variants on disease. The fact that other strains are not as infectious for the rabbit, indicate that there are most likely genetic modifications in the organism which affect virulence. The guinea pig has provided additional research opportunities, especially with respect to the study of the host response, but the current unavailability of inbred guinea pigs makes further experiments problematic as well.

## Herpes Simplex Virus Infection

Since the first description of a creeping virus now known as herpes simplex virus (HSV), a tremendous amount of research has been completed including the establishment of a number of extremely well characterized and successful animal models. Many aspects of the human infection have been effectively modeled in several animal species as reviewed in detail by others.<sup>135–140</sup> This section of the chapter will briefly cover modeling in non-human primates and will highlight the success with the two more commonly used animal species, mouse and guinea pig and finally will describe the potential utility of a cotton rat model of genital HSV-2 infection. Although not discussed here, there are a limited number of reports of modeling atypical HSV-2 disease including ocular infection<sup>141,142</sup> and skin disease.<sup>143</sup> In a small number of reports, studies of interventions, preventatives or vaccines were completed in multiple species, often with the goal of satisfying the “two animal rule” prior to clinical trial evaluations. Such studies provide the opportunity to validate the utility of each animal model as well as identify distinctions that could confound decisions for compound prioritization. It is reasonable to note that the promiscuous nature of HSV allows this virus to infect a variety of species and most all cell cultures studied. As such, recent research to prioritize promising interventions and vaccines is being completed in enhanced human cell culture systems prior to evaluation in animal models. Such cell culture studies subscribe the three R's of animal research (refine, reduce, replace) but do not adequately substitute for compound evaluation in the context of interacting immune and epithelial target cell systems.

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Non-Human Primate

Limited studies have been completed with HSV-2 in non-human primates in part due to the success with the smaller animal models that offer greater availability and lower costs. A single report of genital challenge with HSV-2 in owl monkeys (*Aotus trivirgatus*) indicated that animals, immunized with mixtures of HSV-1 and HSV-2 glycoproteins, were not protected against genital HSV-2 challenge.<sup>144</sup> These animals displayed symptomatology similar to human disease but were not extensively followed for recurrent disease or shedding of reactivated virus. A separate study that examined HSV-2 infection in adolescent and adult female Cebus monkeys (*Cebus albifrons*) indicated that vaginal inoculation of a laboratory strain created a mild, self-resolving primary disease that effectively modeled human infections.<sup>145</sup> All of the 16 adolescent animals and 19 of 21 adults developed clinical disease signs and shed virus over a 3-week period. The other two adults remained resistant to subsequent challenges. The report indicated that only three episodes of recurrent lesions were observed in the infected animals with more showing sub-clinical shedding following vaginal sampling. The authors concluded that the adolescent animals were more susceptible to latent infection using the outcome measures available at that time.<sup>145</sup> An evaluation of the host immune response in these animals suggested they effectively modeled the human response to infection as will be discussed below.

### Mouse Model

In general, mice are highly resistant to intravaginal HSV challenge and, as is the case for other STI, can only be consistently infected through hormonal conditioning with progesterone.<sup>138</sup> Most commonly, animals are conditioned with one or two injections of Depo-Provera beginning roughly 1 week prior to viral challenge.<sup>136,138,140</sup> The challenge dose utilizes  $\sim 10^4$  plaque forming units of clinical or laboratory strains of HSV-2 delivered vaginally after the epithelium is swabbed to remove debris and potentially create microabrasions to serve as portals of entry. This approach consistently led to a lethal infection in >95% of test animals. Given the availability of mice, it has been possible to examine viral kinetics in tissues along the path of infection in the host that is not possible in humans. After inoculation, HSV-2 replicates in the genital tract followed by rapid (<2 days) movement to the peripheral nervous system via sensory nerves. Unfortunately, in mice the infection progresses to the central nervous system; and without intervention, a fatal encephalitis results in nearly all of the infected mice. This is in distinct contrast to the human infection that rarely causes lethal outcomes following genital infection and is a primary disadvantage of the mouse model. The model does provide a very predictable disease course that occurs in all tested outbred and inbred strains of mice. Within 2–3 days of primary inoculation, mice experience hair loss and

erythema near the vaginal os but show minimal skin lesions. As the infection advances loss of bladder control can lead to chronic urine release with fatal outcomes by 7–15 days post-inoculation. In animals that survive the primary infection by vaccination or by antiviral intervention, the virus establishes latency in sacral ganglia but the animals do not show spontaneous recurrent skin lesions nor do they shed reactivated virus.<sup>140,146</sup>

Although the mouse model of genital HSV infection does not ideally mimic human disease, it provides several advantages that make it an excellent small animal system for study of vaccines to protect against lethal outcomes. The mouse model has been used widely to evaluate host immune responses as discussed below.<sup>136,147</sup> The mouse also provides distinct advantages for testing of topical and systemic interventions and preventative compounds including: (i) a mucosal route of viral challenge, thus the agent's ability to interfere with infection at the portal of entry can be evaluated; (ii) both clinical (incidence of signs and mortality) and virologic (isolation of virus from the genital tract) endpoints for evaluating efficacy can be assessed easily; (iii) there are abundant reagents to test both innate and acquired immune responses, and (iv) a disease course that is relatively rapid and therefore inexpensive.

The study of topical preventatives, referred to as microbicides, has made wide use of the mouse model to prioritize the compounds in the pipeline. Plant-based humanized antibodies,<sup>148</sup> natural products,<sup>149</sup> and synthetic TLR agonists<sup>150–153</sup> as preventatives for genital HSV-2 have all been evaluated in the mouse model. A recent approach tested in the mouse capitalized on siRNA technology and the expression of such molecules in the vaginal epithelium that models many aspects of the human tissue.<sup>154</sup> This study showed a durable protection due to the virally delivered siRNA that interfered with HSV-2 infection.<sup>154</sup> Importantly, the mouse model also has been used for safety testing of topical compounds that in some cases created a paradoxical increase in susceptibility.<sup>155</sup> In such studies a variety of methods have been established to assess the impact of the topical applicant upon the integrity of the vaginal epithelium including imaging (colposcopy), innate immune responses (cytokine elaboration into the vaginal cavity), and susceptibility to reduced challenge doses of HSV.<sup>155</sup> Collectively, studies of these topical compounds delivered directly to the vaginal mucosa in the mouse have identified the most promising compounds for study in other animal models and clinical trials.

With the advent of genetically modified animal lines, the mouse model also has provided a system to evaluate the role of host genes on HSV-2 pathogenesis.<sup>156–165</sup> This work has been advanced quickly by the abundance of transgenic and genetic knock-out mouse strains. As an example of this use of the mouse model, work by Spear and colleagues has identified several alternate cellular receptors that are involved in genital tract infection.<sup>164</sup> Using HSV-2 infection of specific knock-out mice, several routes of cellular entry of genital epithelia have been identified helping direct development of novel preventatives designed to block receptor binding.<sup>164</sup> Specifically, the absence

of the primary HVEM or secondary nectin host proteins alone did not prevent genital tract infection. Double knock-out mice were found to have virtually undetectable levels of infection of the genital epithelium. These studies necessarily need to be validated as there are indications that some mouse proteins do not provide consistent mimics for human protein interactions with the virus.<sup>166</sup> This approach also has been successful in dissecting the role of the immune response<sup>147</sup> through elimination of an aspect of the acquired<sup>159,161,165,167–169</sup> or innate<sup>157,158,170–172</sup> immune responses.

HSV-2 infection of pregnant women poses additional threats and can lead to serious complications for the neonate. Asymptomatic shedding during pregnancy has been associated with preterm delivery, lower birth weight and, importantly, a severe and often fatal infection of the neonate as it passes through infected tissues.<sup>173,174</sup> The pregnant mouse has been utilized to model this aspect of human genital herpetic disease with some success.<sup>175–177</sup> The majority of animals experimentally infected during pregnancy experienced varying levels of fetal impact that correlated with the timing of challenge relative to day of gestation. Animals infected early in gestation showed frequent spontaneous abortion of the litter while those infected later in gestation experienced difficulties with delivery of healthy pups.<sup>175</sup> Interestingly, among the studies in pregnant mice, there was some discord in the approach to enhancing susceptibility with a suggestion that pregnant mice did not require progesterone conditioning if they were swabbed effectively in advance of vaginal application of HSV-2.<sup>175</sup>

The need to hormonally condition mice prior to infection has provided some insights into the interaction of the virus with the genital epithelium but does not correlate with susceptibility in the humans. There are now several reports suggesting multiple mechanisms that explain why progesterone conditioning creates a more susceptible environment for vaginal HSV-2 infection.<sup>178–180</sup> It is clear that progesterone dominance thins the vaginal epithelium and shifts the immune system into a more “suppressed” state.<sup>181–183</sup> Using ovariectomized mice treated with saline, estrogen or progesterone or a combination of both hormones, Gillgrass and colleagues established that estrogen provided resistance to the tested challenge doses and the progesterone/estrogen-treated animals showed focal infection that slowly advanced relative to progesterone alone.<sup>181</sup> Since those studies, additional work has suggested that estrogen dominance is associated with enhanced immune response to vaccines<sup>184,185</sup> and provides for better activation of genital-associated lymphoid tissues.<sup>182</sup> The role of hormonal-conditioned susceptibility remains a concern for STI modeling in the mouse in general and continues to be a focus of research.

Recently, STI research has utilized the “humanized” mouse as a system for testing the behavior of human pathogens and vaccines in a small animal system manipulated to support reconstitution with human immune system components. Consistency of reconstitution is a concern in these animals but they are argued to provide an effective preclinical system to test compounds prior

to clinical trial. They are being used as a small animal model for HIV-1 infection as discussed later in the chapter. Humanized mice are created using immunodeficient animals generated through radiation exposure or by genetic alteration that then are implanted with CD34+ stem cells isolated from human umbilical cords. Many of these animals develop functional immune cell populations that are able to be educated to recognize specific antigens and to model proper expression of selected cytokines. In a recent study, humanized mice were immunized against HSV-2 and then challenged.<sup>186</sup> The animals were given Depo-Provera and were followed for viral titer through vaginal washes as well as immunologic outcomes including human antibody titer, evaluation of immune cell types present in the vaginal cavity and T-cell proliferation assays.<sup>186</sup> The results suggest that this model may provide an improved preclinical system for STI vaccine evaluation but still fails to address the lethal outcomes associated with HSV-2 infection in mice making therapeutic vaccine and reactivation and recurrent disease evaluations impossible. These aspects of genital herpetic disease are better modeled in the guinea pig.

## Guinea Pig

Genital HSV-2 infection in guinea pigs is remarkably similar to genital herpes in humans and offers several advantages over the mouse model effectively covered in several reviews.<sup>139,140,187–190</sup> Disadvantages to this animal system include limited immunological reagents, incomplete sequence for the guinea pig genome and added costs and labor associated with the care and use of the larger animal. It is of note that additional immunological reagents are being generated for study of the guinea pig making this animal more attractive for future studies. For HSV challenge, inoculation is performed via a natural route (intravaginal or intraurethral) with either serotype and results in a vesiculo-ulcerative genital skin disease that can be quantified using a lesion-score scale.<sup>188</sup> Zosteriform skin disease associated with rectal and/or genital infection also has been effectively modeled in the guinea pig following dermal inoculation.<sup>143</sup>

The pathogenesis of infection in the guinea pig has been well characterized and involves HSV-2 replication in the genital tract followed by spread via sensory nerves to neurons in the sacral root ganglia. The animal engenders immune responses that limit acute infection with resolution of genital lesions by day 14 post-inoculation. The primary infection is rarely lethal and does not require hormonal conditioning of the female animals. Latent infection is established in the sensory neurons that innervate the genital tract followed by periodic reactivation that produces spontaneous recurrent lesions that can be scored daily.<sup>187,188</sup> Quantification of the latent viral DNA burden in the ganglia also provides an opportunity to assess prophylactic approaches to protect the naïve host. Recurrent lesions can be experimentally induced through UV exposure of the anogenital region of infected animals<sup>191–194</sup> and, as reported recently, through stress associated with overnight fasting.<sup>195</sup> Such induced recurrent

disease offers great opportunity for studying therapeutic regimen including vaccines,<sup>144,190,194,196–198</sup> immunomodulators,<sup>152,193,195,199</sup> and antivirals.<sup>200,201</sup>

Perhaps most importantly, the guinea pig effectively models asymptomatic shedding that is believed to be a major means of transmission to the naïve human host. Cervicovaginal swabs can be collected and assessed for HSV-2 through quantitative PCR that allows evaluation of impact upon both frequency and magnitude of shedding.<sup>152,195,197,198</sup> Using this outcome, therapeutic measures designed to reduce vaginal viral titers to reduce the likelihood of transmission can be evaluated. Specifically, viral shedding frequency is based on reactivation in the ganglia while the magnitude of the shedding event likely reflects viral replication at the vaginal mucosa. This system has shown successful therapeutic immunization of latently infected animals with a glycoprotein vaccine that experienced both reduced recurrent disease and sub-clinical viral shedding.<sup>202</sup> Collectively, studies in the guinea pig have shown that immunization does not prevent infection, but can prevent or at least significantly reduce both the primary disease and subsequent recurrences, the latter observation being correlated with a reduction in the burden of the latent virus.<sup>203</sup>

Similar to the mouse model, the guinea pig also has provided insight into the vertical transmission of HSV-2 to neonates.<sup>137,204</sup> In these studies, newborn guinea pigs were inoculated intranasally and followed for disease signs on the skin, eye, and mouth as well as neurological signs indicating infection of the central nervous system common to human neonatal disease.<sup>137</sup> Respiratory infections were common in this model as were disseminated skin infections that responded well to acyclovir therapy.<sup>137</sup> Interestingly, in survivors, spontaneous cutaneous lesions developed indicating recurrence at primary infection sites that were self limited and appeared as effective models of the human infection. In a follow-up study, the age of the newborn and alternate infection routes were evaluated to better model the exposure that occurs during passage through an infected birth canal.<sup>204</sup> The work concluded that the age of the animal was inversely proportional to the onset, severity, and extent of primary disease as well as the duration of recurrent disease. Animals that were inoculated on the skin of the scalp showed the best outcomes while intranasal infections led to the most severe disease states that without intervention were most often fatal<sup>204</sup> effectively modeling the human condition. Subsequent studies, utilizing intranasal inoculation of newborns, tested the impact of acyclovir therapy and/or passive antibody delivery.<sup>205</sup> The results indicated that combination therapy protected the newborns from fatal infection and significantly reduced the duration of skin, eye, and respiratory disease signs and suggested improved courses of therapy for human newborns.

### Cotton Rat

In a single report, the cotton rat (*Sigmodon hispidus*) has been described as an animal model for genital HSV-2.<sup>206</sup> Like the guinea pig, the cotton rat does not require hormonal preconditioning to enhance susceptibility and experience primary disease similar to

humans following vaginal inoculation. The primary lesions resolve followed by limited spontaneous recurrent lesions. Interestingly, Yim and colleagues reported that HSV-2 DNA could be detected in several disseminated tissues including liver, kidney, lungs, and brain that suggest a systemic infection not necessarily observed in humans. Recurrences could be induced by treatment with dexamethasone allowing for therapeutic compound and vaccine studies as indicated above for the guinea pig.<sup>206</sup> Although only reported in a single study, the data from the cotton rat suggest it may be an additional small animal model to study prophylactic and therapeutic intervention strategies for genital herpes.

### HOST RESPONSE

Each of the described animal models has been evaluated for innate, humoral and cell-mediated immunity responses to HSV genital infection. In many cases, the findings directed subsequent human studies and supported the development of therapeutic strategies as noted above. The most substantial data set has been generated in the mouse system where successful characterization of innate, humoral, and cell-mediated immune responses has been completed. Using genetically altered or depleted of selected immune cell populations established that antibody alone was insufficient to protect against vaginal challenge<sup>158,161,163,165,167</sup> and that a variety of cell types played key roles in the resolution of HSV-2 infections.<sup>147,162,168–170</sup> The data clearly indicate a very complicated immune response with contributions from both antibody and cell-based clearance of virus.

With regard to innate immune responses, the identification of toll-like receptors (TLR) directed additional studies in TLR knock-out mice. Such animals have been utilized to examine the recognition of HSV-2 and subsequent innate immune responses and the impact on pathogenesis. TLR2<sup>-/-</sup> mice, infected with HSV-1, suggested a role for TLR2 but not TLR4 in the innate response to herpetic infection. Paradoxically, TLR2<sup>-/-</sup> mice experienced less neuropathology to HSV-1 CNS infection that was explained by a noted reduction in cytokine elaboration and inflammatory outcomes.<sup>172</sup> These and other studies established a role for TLR2 and 9 in HSV-2 responses and led to a number of human clinical correlates of note. Specifically, polymorphisms in selected TLR genes including TLR2 were associated with increased lesion and shedding behavior in infected humans.<sup>207</sup> Clearly, additional research is needed in animal models and in clinical trials to dissect the steps in the initial recognition and response to HSV-2 infection that ultimately condition acquired responses that should impact both establishment of latent infection and subsequent reactivation in the peripheral and central nervous systems.

In the mouse and guinea pig, studies of neural immune responses to HSV-2 have clearly established that there are resident B and T cells in the ganglia where rounds of latency and reactivation occur.<sup>208,209</sup> These studies effectively changed the understanding of immunity in the nervous system that was believed to be devoid of typical immune cell function. Completion

of these types of studies help to refine vaccine development including vaccines designed to be used therapeutically in order to address the latent sites of infection that serve as a reservoir for transmission.

## SUMMARY

HSV genital infections are prevalent in the adult population and are of increasing concern given the association to acquisition of other STIs including HIV-1. Research in animal models has provided much of our understanding of pathobiology of infection as well as refining strategies for prevention and therapeutic interventions. The mouse model offers many advantages including access to essential immune reagents to study responses and vaccine potential. Disadvantages include genetic distinctions in the way that HSV proteins interact with the mouse proteome relative to the human proteome<sup>166,210</sup> and the lethal outcomes associated with HSV-2 vaginal infections in mice. HSV researchers have made great use of the guinea pig model that addresses many of the major disadvantages with the mouse model. In this fashion the combined use of the mouse and guinea pig has provided for the effective use of available immunological reagents for the mouse where the guinea pig options are limited. The need to follow disease resolution and subsequent recurrent lesion development is then addressed with subsequent studies in the guinea pig. As an indication of this paradigm, the guinea pig model was predictive of the efficacy of acyclovir<sup>211</sup> and has been used to evaluate a number of prophylactic vaccine strategies.<sup>212</sup> In addition, it was used to prove the concept of immunotherapy, i.e., the use of therapeutic vaccines to control recurrent disease<sup>213</sup>; an approach extended subsequently to humans through a clinical trial.<sup>214</sup> Finally, guinea pigs that are infected also shed virus from the vaginal cavity at high frequency and in the absence of clinical disease signs. This aspect of the human disease is critical to the study given the role of viral shedding in HSV-2 transmission. The naïve sex partner is unaware of the infected partner's status due to a lack of disease signs despite shedding of significant amounts of virus.<sup>215,216</sup> Together these two main animal models have provided substantial information and have advanced successful approaches to begin to reduce transmission of this important STI.

## HIV Infection

HIV-1 is one of the most difficult STI pathogens to model because of the extremely limited host range of its virus family. The only non-human species that has proven to be susceptible is the chimpanzee. HIV is a member of the lentivirus genus that includes a number of genetically similar viruses with equally limited host ranges.<sup>217,218</sup> Of the identified viruses, several, with varying levels of genetic similarity to HIV-1, provide opportunities for surrogate animal modeling that represent some of the most common and well-characterized systems for research. Although lentiviruses have been isolated from a variety of animal species (see Stump and VandeWoude for review<sup>219</sup>) currently, none have been isolated from a rodent limiting the options for HIV studies

to larger animal models. Over the last decade, two approaches have been initiated to expand the options for HIV modeling in animals. The first involves the production of chimeric viruses that maintain tropism for the animals they were isolated from but have genetic replacements that direct expression of selected HIV genes to enhance study of vaccines and antivirals.<sup>217,220</sup> The second approach is the genetic alteration or xenografting of rodents to enhance their susceptibility to HIV.<sup>221–224</sup> Given these enhancements, there has been a great deal of success on modeling aspects of HIV infection in a limited number of animals as reviewed in detail by others.<sup>219,220,225</sup> The next few pages will highlight the most commonly employed models using HIV surrogate viruses, chimeric viruses, and finally altered rodents. Finally, outside the scope of this section, there are a number of effective pathogenesis models utilizing non-lentiviruses that produce similar disease as reviewed in detail.<sup>219</sup>

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Non-Human Primate Model

Initial studies, just over 2 decades ago, established that the chimpanzee (*Pan troglodytes*) is susceptible to HIV infection.<sup>226</sup> This was a likely outcome given the belief that HIV-1 infection of humans resulted from direct interactions with chimpanzee.<sup>227</sup> Following intravenous delivery, inoculated animals developed persistent viremia but did not develop obvious pathology.<sup>226</sup> Vaginal installation of HIV-1 also led to a persistent viremia in a small number of chimpanzees but again did not cause immunodeficiency.<sup>228</sup> Genital inoculation of pigtail macaques (*Macaca spp.*) created a transient infection that also did not produce disease.<sup>229</sup> A slightly better success rate was established by inoculating “animal-adapted” HIV-2 in pigtail macaques and baboons (*Papio anubis*) that resulted in a reduction in CD4+ cell counts and subsequent AIDS.<sup>229</sup> Unfortunately, in each case the lack of reproducible HIV-1 infection of these costly animals and the minimal or undetectable disease created by the infection led researchers to seek more viable alternatives.

The discovery of simian immunodeficiency viruses (SIVs) substantially advanced the ability to model the pathogenic process associated with HIV-1 infection in humans. SIVs are found commonly in a number of African monkey species and are believed to be close relatives to HIV-1.<sup>219</sup> Interestingly, the African monkey isolates were found to be highly infectious and pathogenic for Asian macaque monkeys (*Macaca mulatta*, *M. fascicularis*, *M. nemestrina*) that developed more pronounced clinical signs similar to human HIV-1 infection.<sup>230</sup> SIV was originally isolated from rhesus macaque (*Macaca mulatta*) monkeys (SIVmac) and was associated with an AIDS-like illness.<sup>231–233</sup> Since the original isolation, SIV strains have been isolated from several animal species including chimpanzees (SIVcpz), sooty mangabeys (SIVsmm), African green monkeys (SIVagm), and mandrill (SIVmnd).<sup>217</sup> Molecular clones have been generated for many of these strains

and have been analyzed for pathogenesis in selected non-human primates.<sup>234,235</sup> As is the case for most of the lentiviruses, extreme limitations in host range were observed for each but several of the SIVmac clones were able to elicit “AIDS-like disease” in Asian rhesus macaques.<sup>231,235</sup>

Of the SIV isolates, the majority of animal modeling of HIV-1 has been accomplished with SIVmac inoculated experimentally into male and female rhesus macaques.<sup>236</sup> SIV has been transmitted experimentally by vaginal inoculation creating a disease state in the infected animals that was similar to that created by intravenous administration of the cell-free virus.<sup>237,238</sup> Subsequent studies with a single vaginal inoculation showed high infection rates as evidenced by persistent viremia independent of the timing of inoculation relative to menstruation.<sup>239</sup> Marx and colleagues did report that progesterone implants enhanced vaginal infection with SIV suggesting vaginal epithelial thickness may impact susceptibility.<sup>240</sup> This finding coincides with clinical observations that women are more susceptible to HIV-1 infections during pregnancy and the associated high levels of progesterone.<sup>241</sup> The model was used to show proof of concept through formalin fixed virus immunization that protected a high percentage of animals from infections.<sup>242</sup> Male macaques also proved susceptible to SIV inoculation through urethral infusion or inoculation of the penile foreskin.<sup>238,243</sup> Limited indications of sexual transmission of an experimental SIV infection also have been reported in pigtail macaques. The infected females that mated with naïve males apparently transmitted the infection but other routes (biting, cleaning, etc) were not excluded.<sup>244</sup> Importantly, SIVmac also models aspects of HIV infection of the gut and nervous systems.<sup>245–249</sup> The SIV/macaque model system provided insight into HIV-1 vertical transmission and transmission via breast milk.<sup>238,250–252</sup> Finally, as a model of rectal transmission, male rhesus and pigtail macaques were successfully infected by intrarectal installation of cell-free virus leading to a persistent viremia.<sup>253,254</sup>

Although a substantial step forward, the SIVmac model lacked the capability to fully address the unique accessory functions encoded by HIV-1 and the pathology elicited in experimentally infected macaques was not sufficient to fully model all aspects of the human disease. In addition, SIVmac clones share 30–50% genetic identity with HIV-1 with substantial dissimilarity localized to the envelope glycoprotein impacting the value of modeling of antibody responses and vaccine evaluations. To address some of the shortcomings, molecular chimeras of SIV and HIV (designated SHIV) were created and utilized in several non-human primate species.<sup>217</sup> A subset of the chimeras, that express the HIV glycoprotein and accessory genes, retains the ability to infect the original non-human primate species but better model the HIV-1 life cycle and human infection. Several genetic approaches were taken but the most successful also included serial passage through either cultured monkey cells or macaques.<sup>255</sup> Such SHIV isolates are now the mainstay for use in animal models where mucosally inoculated macaques develop persistent viremia, experience a loss of CD4 cells and subsequently develop the SIVmac AIDS-like

disease.<sup>256–259</sup> The success with this challenge model has made this system the most frequently employed to evaluate HIV-1 vaccine candidates. With addition of the HIV-1 reverse transcriptase into successful chimera the system also has been used to evaluate antiviral regimen and emergence of drug resistance.<sup>260,261</sup> This model system also has provided important information about the production of envelope-neutralizing antibodies<sup>262</sup> and the potential for passive immunization methods to alter pathogenic outcomes of SHIV infection.<sup>263,264</sup>

In general, the SIV or SHIV infections of mucosal surfaces results in an acute viremia and depletion of CD4 cells albeit under distinct timelines. For SHIV, CD4+ T-cell depletion occurs within weeks of inoculation leading to AIDS in a few weeks to 2 years in this animal model; this does not effectively model human HIV-1 infection and subsequent AIDS development (~10 years).<sup>265</sup> Further, study of the less successful chimera helped identify several macaque proteins that provided levels of resistance to SHIV providing important insights to the failings in the human host response to HIV-1.<sup>217</sup> This and other issues pushed the development of the next generation of SHIV chimeras that essentially start with HIV-1 and introduce necessary genetic elements to support infection of and replication in monkey cells. Several such chimera have been reported in the last few years that are ~90% HIV-1 but have the necessary SIV elements to overcome the host restrictions at least in cell cultures of macaque cells.<sup>266–268</sup> In a recent *in vivo* study, one of the next generation SHIV successfully infected 4 pigtail macaques creating a viremia that declined over time and did not cause the depletion of CD4+ cells.<sup>269</sup> These promising approaches will require additional work but show great promise to further enhance the utility of this animal model system.

## Feline Model

Another member of the lentivirus genus, feline immunodeficiency virus (FIV), was identified in domestic cats that presented with immunodeficiencies (leukopenia) and other disease signs.<sup>270</sup> Unfortunately, at a genetic level, FIV is more similar to ungulate lentiviruses than those isolated from primates.<sup>271</sup> Unlike SIV, FIV is naturally T-cell tropic and provides the opportunity to better model the interactions between this lentivirus and the T-cell target. FIV infects both CD4+ and CD8+ T cells.<sup>272</sup> Importantly, FIV infects target cells through interactions with the CXCR4 entry receptor and the CD134/OX40L binding moiety that are primarily expressed on CD4+ T cells.<sup>273,274</sup> As such the binding and entry of FIV are similar to HIV-1 as are some aspects of the transmission process including vertical transmission to kittens during gestation and suckling.<sup>275–277</sup> In adult animals, FIV is primarily transmitted through biting or cleaning behaviors but has been experimentally delivered via transfusion of infected blood.<sup>278</sup> Interestingly, although FIV can be isolated from a variety of non-domestic felines, only domestic cats show clinical signs consistent with HIV-1 infections.<sup>278</sup>

Infected cats experience a prolonged acute phase viremia and clinical signs including lymphadenopathy, anorexia, gingivitis, cachexia, and an increased susceptibility to opportunistic infections.<sup>278</sup> In infected cats, the CD4:CD8 ratio declines, similar to HIV-1 infected humans and, over time, a CD8 rebound is reported and FIV-specific antibody titers increase.<sup>279</sup> Experimentally infected cats also show low T-cell levels at mucosal surfaces and are highly susceptible to subsequent challenge with a variety of opportunistic pathogens. Domestic cats have been infected by a number of routes including most mucosal surfaces. Considering the female animal and a model of sexual transmission, 10 of 11 cats were infected by vaginal inoculation with a relatively high dose of FIV.<sup>280</sup> This report also documented that a leading microbicide at the time, Nonoxynol 9 (N9), could be applied to cats prior to inoculation to protect them from infection.<sup>280</sup> Isolates from each of three FIV clades, A, B and C, have all established experimental infections in domestic cats.<sup>279,281</sup> In 2002, a clinical license was granted for a vaccine against FIV in domesticated cats and has been used to support the likelihood of successful vaccine development for other lentiviruses.<sup>282</sup>

Although useful for specific studies, a major disadvantage to this HIV surrogate animal model system is the dramatic differences in the feline reproductive system relative to human females. The anatomy of the cat's genital tract is substantially different from the human with a cornified vaginal epithelium that changes substantially during the estrus cycle of the animal.<sup>135</sup> This may have contributed to the success of the N9 trial that was found to enhance susceptibility due to vaginal epithelial damage.<sup>283–285</sup> Another concern for the model is the availability of pathogen-free cats. Despite these disadvantages, there are a number of directed uses for the system including screening of topical antivirals and vaccine evaluation. Finally, the neurotropism of and neuropathology associated with FIV make it a useful model system to study those aspects of HIV-1 infection in humans.<sup>286–288</sup>

## Transgenic Rat Model

As noted previously, rodents have not proven susceptible to lentiviral infection and as such have not been useful model systems. To enhance the potential for these more convenient, smaller animals, transgenic technology has been employed to create Sprague–Dawley rats that express human CD4 and CCR5 that serve as the main receptors for HIV infection of T cells. The initial animals were engineered to express both human proteins selectively on CD4 T cells, macrophage, and selected neural tissue cells that represent main target cell types for HIV-1 infection.<sup>289</sup> This initial model allowed for persistent harboring of HIV-1 after systemic challenge and allowed for an efficacy study of an entry inhibitor<sup>290</sup> but failed to generate a prolonged viremic state showing low but detectable serum levels of virus.<sup>289</sup> Interestingly, these studies identified that the model allowed for substantial entry of virus but most of the transgenic target cells were not supportive of early HIV-1 gene expression.<sup>290,291</sup> Similar to the

work noted above in macaques, use of this animal model allowed the identification of another rat protein as a inhibitor of HIV-1 replication. Specifically, a critical role for cyclin T1 (CycT1) in the elongation steps of HIV-1 transcripts was identified and was a major impediment for implementation of the transgenic rat system.<sup>222</sup> To overcome this limitation, additional genetic material was introduced to the existing transgenic rat such that cell-specific expression of human CycT1 was accomplished.<sup>222</sup> Although the transgenic expression of CycT1-boosted HIV-1 gene expression sustained viremia and pathologies were not observed indicating that additional work will be required to make this system a fully useful animal model for HIV-1 infection. Interestingly, similar work is being pursued in transgenic mice with extremely different outcomes.<sup>292</sup>

## Humanized Mouse Model

The pioneering work of several groups of researchers established a number of mouse models that capitalized upon animals that were genetically deficient in key aspects of the immune system. As such, these CB-17 severe combined immunodeficient (SCID)<sup>293</sup> mouse lines stably accept immune system reconstitution by xenografting of human cells or tissues. SCID mice lack B and T-cell function but retain much of the innate immune response including natural killer (NK) cells. Several derivatives have been created that have enhanced the ability to create more useful humanized mice as will be discussed below.<sup>294</sup> Based on the human xenografting, varying degrees of HIV-1 target and response cell production is created earning these manipulated animals the moniker “humanized mice.”<sup>295–297</sup> These animals are being used widely for HIV-1 modeling as well as a number of other difficult to model human pathogens. Recent and thorough reviews by Denton and Garcia or Hoang and colleagues provide detailed and extensive overviews of the successes and failures with these models.<sup>223,224</sup> In the next few paragraphs the highlights of each of the three main mouse systems will be covered in the context of HIV-1 infection and response.

The original humanized mice utilized SCID animals that were injected intraperitoneally with peripheral blood lymphocytes (PBL) that provided a transient presence of human immune cells including B and T cells.<sup>297,298</sup> As an alternative, the non-obese diabetic SCID mouse (NOD/SCID) with reduced NK cell function also has been utilized because it is more supportive of engraftment.<sup>299</sup> Injection of human PBL in either SCID or NOD/SCID mice produced a transient (weeks) presence of mature human T and B cells that quickly waned<sup>300,301</sup> due to a lack of progenitor cells. The mature cells were most often in circulation making some natural routes of infection less reliable (e.g., vaginal). One group reported a better success rate with vaginal inoculation of SCID-hu PBL mice following progesterone conditioning.<sup>302</sup> This severe limitation allowed proof of concept and limited studies of viral cytopathic effects and vaccines but did not allow for accurate modeling of human response to HIV-1 infection. The presence of B cells in the system was exploited for

several vaccine evaluations.<sup>303–306</sup> The advantage of this system is that the mouse can receive PBL from individuals that have been vaccinated to evaluate the potential of specific vaccines. At the very least, SCID-hu mice provided a first susceptible mouse model for HIV-1 infection<sup>302,307</sup> supporting further refinements in HIV-1 humanized mouse models.

To create a longer-lived engraftment, human fetal liver and thymus tissues were implanted in the kidney of SCID animals (SCID-hu Thy/Liv) to create a hybrid organ that provided a renewable source of immune cells. The SCID-hu Thy/Liv model originally was created to allow for modeling of human hematolymphoid cell differentiation<sup>296,308,309</sup> but provided improved options for HIV-1 infection modeling. Histologically, the hybrid organ established proper architecture for the thymus and was found to be vascularized and viable over time. The tissue allowed for prolonged production of immune cells (months) that unfortunately were released into systemic circulation at extremely low levels. In fact, most of the human cells were localized to the Thy/Liv tissue graft reducing options for HIV-1 inoculation routes and requiring direct injection of HIV-1 into the graft. Interestingly, the tissue produced expected cell populations including CD4, CD8, and a variety of other T-cell populations that were tolerant to the mouse “self antigens,” indicating an education function.<sup>310,311</sup> Unfortunately, few human B cells, macrophage and dendritic cells could be detected. Additionally, the sequestering of the human immune cells precluded study of natural routes of HIV-1 infection (e.g., genital tract) and limited the utility of the model for vaccine or other intervention evaluations. The system was useful for assessing antivirals<sup>312</sup> and the impact of genetic alterations in HIV-1 to evaluate the role of selected genes.<sup>313–316</sup>

In the 20 years since the first humanized mice, the models have been further refined using progeny generated from subsequent crosses with more substantial immunodeficits. The other lines include recombinase activating gene (Rag2<sup>-/-</sup>) knock-out mice and interleukin receptor gamma chain (ILg<sup>c</sup>-/-) knock outs.<sup>294</sup> Rag<sup>-/-</sup> animals are considered superior to SCID mice due to a complete lack of capacity for producing B or T cells and a substantially higher rate of engraftment that reduced variability in the humanization.<sup>294</sup> ILg<sup>c</sup>-/- mice have a severely crippled innate immune response that impacts proper development of acquired immune responses. Crosses with SCID, NOD, and between the lines have produced animals that lack innate and acquired immunity providing an ideal host strain for human immune system engraftment. Using such animals as newborns or adults, another refinement has been made with the advent of CD34+ hematopoietic stem cells (HSC). The HSC act as immune system progenitor cells and, when injected intravenously, intrahepatically or intraperitoneally, can create functional immune organs and cell lineages.<sup>317–321</sup> Following intrahepatic injections, the HSC develop functional human B, T, and dendritic cells including human cells that populate the mouse thymus where they are educated to be tolerant of mouse MHC.<sup>321</sup> These humanized mice have been infected with HIV-1 where persistent viremia,

reduced CD4 cell numbers in blood and thymus and a robust anti-HIV antibody response were observed.<sup>322–325</sup> Importantly, these animals could be infected with HIV-1 via genital or rectal routes common to HIV-1 infection in humans.<sup>324</sup> Although a tremendous step forward modeling HIV-1 infections in a small animal, there are still several concerns with the models regarding robust immunoglobulin responses important to vaccine evaluations and HIV-1 infection of the nervous system and the recently recognized gut-associated lymphoid tissues (GALT) that play an important role in human infection.<sup>326,327</sup>

To address some of these additional concerns, a final refinement has been reported that is a labor-intensive approach to more fully reconstituting a human immune system in these severely immunodeficient mice. The NOD/SCID BLT mouse is considered to be the most advanced model system to date and involves the engraftment of human fetal liver and thymus in the kidney followed by transplantation of autologous CD34+ HSC providing long-term reconstitution of functional lymphoid and myeloid cell lineages.<sup>328–330</sup> BLT mice can produce human immunoglobulin appropriate to challenges or immunization<sup>329,331,332</sup> and support HIV-1 infections via several routes.<sup>333,334</sup> Infected animals produce human antibody against HIV<sup>334</sup> and have been used for antiviral testing following vaginal inoculation.<sup>333</sup> Importantly, the BLT mice have been reported to have a properly colonized GALT, lung, and female reproductive tract making them an attractive alternative for HIV-1 research.<sup>329,333,334</sup>

## HOST RESPONSE

As noted several times, the limited host range of HIV-1 has made modeling of host responses one of the most difficult aspects of this work. Further, the lymphotropic nature of the HIV-1 infection that allows the virus to subvert the immune system by infecting the cells responsible for many aspects of the host response contributes to the difficulties. Non-human primates infected with SIV and SHIV have provided indications of the role of T cells in the response and have indicated novel directions for study in humans. Recently, the trafficking of monocytes and macrophage associated with the development of encephalitis has been compared between non-human primates and clinical conditions.<sup>335</sup> Unfortunately, the SIV macaque models have been able to provide only limited insight into immunoglobulin responses due to the genetic differences in the envelope. The chimeric viruses that are primarily HIV-1 (including *env*) with necessary SIV elements should provide greater insight into the types of antibody that are effective at resolving HIV as well as identifying the epitopes that should be targeted by future vaccines. Perhaps the greatest likelihood of success in this regard will come from the humanized mouse systems that will allow the modeling of specific human responses to HIV-1.

In the SIV/macaque model, infected animals show relatively quick and robust antibody responses as well as non-specific increases in CD8 numbers and NK cell activity in the blood.<sup>336</sup> Cytotoxic lymphocytes are detected in infected animal mucosa

within 3 weeks of inoculation but appear to develop too late or are too limited to effectively resolve the infections.<sup>225,337</sup> Interestingly, it was reported that vaginal infection led to a different emergence of virus-specific T cells that was suggested to be an indication of altered homing.<sup>338</sup> As seen clinically, the immune responses in macaques infected with SIV or SHIV decline over time as the CD4 cell counts diminish.<sup>225</sup> As noted above, the onset of AIDS in infected monkeys is sooner than in human patients further complicating study of the host responses.

As a model of HIV-1 neurological sequelae, FIV infection of domestic cats provides some likely indications of human host responses. All FIV isolates cause neuropathologies that include immune cell infiltrates and gliosis in the midbrain and thalamus.<sup>288,339</sup> Immune responses are activated during the infection and can exacerbate the neuropathology observed and can lead to B cell, CD4, and CD8 cell infiltration of the nervous system.<sup>286</sup> Study of these responses has helped address some of the issues with human neuroAIDS. Finally, the success with a vaccine for FIV has suggested this system may be of great value for directing vaccine work but immune reagents for such studies are lacking. Again, the humanized mouse or the transgenic rabbit, rat or mouse may provide the necessary advancement and available reagents to address the shortcomings in the non-human primate models.

## SUMMARY

By its very nature, HIV-1 presents some of the most difficult aspects for animal modeling of all the STIs. The limited host range of the family of lentiviruses and HIV-1's cell tropism also add to the modeling issues. Despite these shortcomings, researchers have made substantial progress in understanding the virus, the role of key genetic functions, establishing systems for evaluation of antivirals and vaccines using the few available animal systems. It is of note that the creativity of the researchers modeling HIV-1 in animals has led to some major advances for STI research including the advent of chimeric viruses and the humanized mouse. It is even more remarkable given the very recent emergence of this STI.

## Trichomoniasis

While genital infections with *Trichomonas vaginalis* are highly prevalent, there has been a paucity of research using animal models, largely for similar reasons to other animal models for sexually transmitted infections in which the etiologic agents have a high specificity for the human host. An abscess model in the mouse can be induced by intraperitoneal or sub-cutaneous injection<sup>340</sup>; nevertheless, this model does not bear relevance to vaginal infection. Analogous to other models discussed in this chapter, the key factor to establishing trichomonas infection in animals was the manipulation of the hormonal balance. However, since this infection is primarily one of the vaginal infection, it was important to consider the nature of the normal flora and the vaginal pH in the animal model in order to establish infection.

## DESCRIPTION OF THE MODEL AND RELATIONSHIP TO HUMAN DISEASE

### Non-Human Primate

Successful infection of non-human primates was first accomplished by Gardner and colleagues when they inoculated squirrel monkeys (*Saimiri sciureus*) with a single inoculum of  $5 \times 10^5$  *T. vaginalis* cells.<sup>341</sup> Because squirrel monkeys have a trichomonas species as normal flora in the gut, the animals were treated with metronidazole prior to inoculation with *T. vaginalis*. Infection of the animals was only accomplished when they were inoculated during breeding season because they had elevated levels of estradiol, with two of the animals remaining positive for 4 weeks until becoming negative as estrus waned. Microscopic examination of tissues demonstrated an acute and chronic inflammatory response primarily at the squamocolumnar junction of the vagina and cervix.

The only other attempt to develop a non-human primate model was published by Patton and colleagues.<sup>342</sup> In this study, they inoculated pigtailed macaques (*Macaca nemestrina*) with  $6.6 \times 10^5$  trichomonads intravaginally. A high rate of infection was demonstrated with organisms persisting in the majority of the monkeys for up to 5 weeks after which the experiment was terminated. The vaginal pH varied from 5.5 to 8.0 but appeared to be dependent upon the stage of the estrous cycle. In addition, there was no obvious effect of the infection on the normal flora of the animals. In 3 of 8 animals examined by colposcopy, tissue irritation was observed but no "strawberry" cervix as observed in humans. Thus, this model is able to demonstrate consistent infection and has the potential for use in the study of the pathogenesis of infection as well as in the evaluation of topical microbicides and other therapeutic measures.

### Mouse Model

The mouse has been a more difficult animal in which to establish a genital tract infection with *T. vaginalis*. The key to producing a successful infection was the pretreatment of mice with estradiol but the infection could be further enhanced by modifying the normal flora of the mouse.<sup>343,344</sup> Therefore, BALB/c mice were injected subcutaneously with 10 mg/mL of estradiol valerate 2 and 9 days prior to inoculation with *T. vaginalis*. In addition, mice were inoculated with  $10^9$  CFU of *Lactobacillus acidophilus* intravaginally 7 days prior to inoculation with trichomonads. When compared to mice not populated with lactobacilli, there was no difference in the number of mice becoming infected; however, a significantly higher percentage of animals remained infected for at least 24 days after inoculation.<sup>343</sup> Infection in the control mice declined by day 12 and majority of the animals resolved their infections by day 21.

### HOST RESPONSE

Thus, so far there has been only minimal work done on the host response to vaginal infection with *T. vaginalis*. Humans do not

appear to develop immunity to reinfection, and it appears that the mouse mimics this as well. Abraham and colleagues infected mice intravaginally and then treated the mice with metronidazole at 14 days to resolve the infection with the intent of inducing a protective response.<sup>345</sup> However, upon challenge there was no difference in the infection rate or course of infection in the treated mice versus naïve mice, suggesting that immunity did not develop as a result of infection. Interestingly, sub-cutaneous immunization of mice with varying doses of viable trichomonads did result in a protective response and did appear to be correlated with IgG antibodies in sera and secretions. Thus, it was possible to elicit a protective response but genital tract infection alone does not appear to be sufficient.

## SUMMARY

As is apparent from the dearth of literature on animal models of vaginal infection with *T. vaginalis*, there remains a great deal to be done. Nevertheless, the non-human primate and mouse models are potentially useful in the study of the pathogenesis of infection and investigation into possible mechanisms by which the organism apparently avoids a protective host response.

## Co-infection Models

An area that has received little attention but which is very important in the modeling of sexually transmitted infections is the infection of animals with more than one STI agent, obviously, an event that commonly occurs in humans. The following represent initial studies on models of co-infection which will allow for the quantification of the impact of a pre-existing sexually transmitted infection on susceptibility to a second STI. Results of such modeling should help direct subsequent clinical research and may lead to novel approaches of protection against infection as well as the potential influence on disease elicited by each agent.

## CHLAMYDIA SPP./HSV-2

The development of mouse models for vaginal HSV-2 and *Chlamydia spp.* infections that both utilize progesterone preconditioning offers the opportunity for the study of pre-existing infection of one on the other. There have been a number of associations made suggesting genital herpes enhances susceptibility to other pathogens including HIV as a result of the HSV-2-induced vaginal ulceration but few studies have examined the impact on pre-existing STI infection on HSV-2. To study the impact of chlamydial infection on HSV-2 challenge, mice were inoculated with approximately  $1 \times 10^6$  IFU of *C. trachomatis* human serovar E or *C. muridarum* after standard progesterone conditioning. In parallel, a group of similarly conditioned animals was mock inoculated with equal volumes of PBS. Animals were swabbed on day 3 post-infection and assessed by PCR<sup>346</sup> for active chlamydial infection. Three days later (day 6 post-infection) each animal was challenged with HSV-2 and followed for vaginal

viral titer and disease signs. The results indicated a substantial reduction in HSV-2 vaginal titer and disease signs in those mice that had evidence of chlamydial infection regardless of the species (N Bourne and RB Pyles, unpublished data).

## NEISSERIA GONORRHOEAE/CHLAMYDIA

The development of a mouse model to study gonorrhea and chlamydia co-infection is challenged by the fact that female mice are susceptible to *N. gonorrhoeae* and *C. muridarum* at different stages in the reproductive cycle. Recently, a mouse model was described in which mice are first colonized with *C. muridarum* and then challenged with *N. gonorrhoeae*. Interestingly, the number of gonococci recovered is reproducibly higher in *C. muridarum*-infected mice compared to mice inoculated with *N. gonorrhoeae* alone. The vaginal neutrophil response is also higher in co-infected mice than in mice infected with either single pathogen. These results suggest a pre-existing chlamydia infection may promote increased survival or replication of *N. gonorrhoeae* and thus increased susceptibility to gonorrhea (RA Vonck, T Darville, CM O'Connell, and AE Jerse, personal communication). This model should be a valuable system for studying interactions between *Chlamydia* and *N. gonorrhoeae* *in vivo* and the host response to co-infection with these two common pathogens.

## Acknowledgement

The authors would like to thank Dr. Ann Jerse for reviewing a portion of the manuscript.

### Summary

The use of animal models for the study of sexually transmitted infections has been critical to our understanding of the pathogenesis of disease and host response to infections as well as the development of intervention and prevention modalities. Nevertheless, none of the animal models are exact substitutes for the human disease, so that in some cases it has been difficult to extrapolate data obtained in the animal directly to the human situation. Thus, the use of specific animal models requires that one understand how the models differ from human disease as much as how they are similar, e.g., whether a different microbial species is used, whether there are significant differences in the physiology of the host compared to humans, or whether the kinetics of the infection are different. For some infectious agents, more than one model is available, with each mimicking a part but not all of the disease as it presents in humans. In such situations, it is important that the investigator understands which model will best answer the particular question being asked and be aware that not every model can answer every question. Choosing the wrong model for a given problem will very likely provide misleading information. The purpose of this chapter is not only to describe the animals models used for the various STIs, but also to present the advantages and disadvantages of the various models and how the models can be applied to understand human disease. This information should aid the investigator in not only interpreting animal model data in the context of human disease but also provide the researcher with the information necessary to choose an animal model for their work.

## **GUIDELINES FOR THE MANAGEMENT OF SEXUALLY TRANSMITTED DISEASES AND HIV**

— *Basil Donovan*

Guidelines for the Management of Sexually Transmitted Infections	1299
Guidelines for the Treatment of HIV in Industrialized and Middle Income Countries— Adults, Adolescents, and Pediatric	1310
Guidelines for the Treatment of HIV and AIDS in Resource-Limited Countries	1328
Guidelines for Prevention of Perinatal HIV Infection	1345
Guidelines for the Management of HIV-Associated Opportunistic Infections	1358

"This page intentionally left blank"

## Introduction

Effective management of sexually transmitted infections (STIs) is an important component of STI control, as it reduces the further transmission of infections, prevents the development of complications, and serious long-term sequelae. Rapid and effective treatment of STIs also leads to the reduction in the transmission of the human immunodeficiency virus (HIV).<sup>1,2</sup>

Provision of appropriate treatment of STIs at the first contact a patient has with a healthcare provider is an important public health intervention as it reduces the infectivity of the patient and allows for the provision of behavior change communication, while there is the potential to influence future sexual behavior and treatment-seeking practices. The World Health Organization strongly recommends that all countries develop and use standardized treatment protocols for STIs.<sup>3</sup> Having such guidelines ensure that all patients receive adequate high-quality care at all levels of the health service. In addition, standardized guidelines facilitate the training of care providers and the procurement and distribution of antimicrobial agents. The use of standardized treatment recommendations at the national level helps to reduce the risk of development of resistance to antimicrobials.

Recommendations described in this chapter will help countries to develop standardized protocols that are adapted to address local epidemiological and antimicrobial sensitivity patterns. It cannot be over-emphasized that it is essential that antimicrobial susceptibility of STI pathogens are monitored closely as pathogens resistant to recommended antimicrobials may emerge spontaneously or may be imported from other parts of the world.

## STI Case Management

STI case management is the provision of the complete care “package” to a person with an STI that may have been diagnosed syndromically or after laboratory tests have been performed. The components of case management include:

- history taking;
- clinical examination;

- making a diagnosis, which may be syndromic or etiologic;
- provision of effective treatment;
- provision of behavior change communication, including: information on the nature of infection, acquisition and transmission of infection, prevention of infection, and advice on safer sexual behavior;
- promotion and provision of condoms, together with education on the correct use of condoms and their hygienic disposal;
- partner notification and treatment;
- case reporting; and
- clinical follow-up as appropriate.

Thus, effective case management consists not only of antimicrobial therapy to obtain cure and reduce infectivity, but also comprehensive consideration and care of the patient’s reproductive health.

## Syndromic Management of STIs

The diagnosis of STIs may be made upon the laboratory identification of a sexually transmissible pathogen or on the recognition of the pattern of symptoms and signs an infected person presents with.

Making an etiologic diagnosis based upon identifying the pathogen requires laboratory testing, and this is problematic for healthcare providers in many settings, especially in the primary healthcare setting where the infected person first presents for care. Laboratory testing places constraints on time and resources, increases costs and reduces access to treatment. It is also dependent on the availability of appropriate laboratory tests. Currently only a few tests that have high sensitivities and specificities that can be performed at the point of care are available commercially. Hence the making of an etiologic diagnosis requires that specimens be collected and sent to central level laboratories for processing. This results in unacceptable delays in providing the patient with care. Laboratories require suitably qualified personnel with adequate training to perform technically demanding procedures, and the establishment of external quality control must be made mandatory.

The syndromic management approach is based on the identification of consistent groups of symptoms and easily recognized signs (syndromes), and the provision of treatment that will deal with the majority of, or the most serious, organisms responsible for producing a syndrome. WHO has developed a simplified tool (a flowchart or algorithm) to guide health workers in the implementation of syndromic management of STIs.

Many healthcare facilities in developing countries lack the equipment and trained personnel required for etiological diagnosis of STIs. To overcome this problem, a syndrome-based approach to the management of STI patients has been developed and promoted in a large number of countries in the developing world.

Readers are advised to read Section 9 on the syndromic management of sexually transmitted infections, which describes the approach in greater detail.

### SELECTION OF ANTIMICROBIAL REGIMENS

When selecting antimicrobial regimens for specific STIs, a number of important points need to be considered. These include drug efficacy, drug safety, the cost of the drugs, and acceptability of the recommended regimen to the patient in order to ensure treatment compliance, local availability of the drugs, and the effect of the drug regimen on co-infections.

#### Drug Efficacy

An important criterion when selecting an antimicrobial is the effectiveness of the drug in treating the infection. Ideally the recommended drug regimen should cure at least 95% of those with the infection. Drug regimens with lower cure rates of between 85% and 95% should be used only with caution as such treatments may select for resistant strains and therefore rapidly limit their usefulness. Regimens with lower cure rates should not be recommended.<sup>3</sup>

Often efficacy data cannot be transferred reliably from one population (or in some situations, from one sub-population) to another. Therefore, ideally, recommendations should be based on well-designed therapeutic trials conducted locally. Of course, this will depend on the local availability of expertise and financial resources to conduct such trials. In such situations, recommendations may be based on evidence obtained from studies conducted within the region.

Therapeutic efficacy of antimicrobials should be monitored; this requires periodic studies of clinical efficacy and laboratory monitoring for antimicrobial susceptibility of STI pathogens.<sup>4</sup>

#### Drug Safety

The safety of recommended drugs is an important consideration when developing treatment guidelines. The occurrence of adverse drug reactions is not in general predictable and reactions range from minor discomfort to major life-threatening events. However, there is always a need to keep this in mind when making recommendations. Intolerance to drugs often leads to non-compliance with treatment regimens and hence infected patients may only be partially treated and risk further transmission of

infection as symptoms may be masked. It should also be noted that combination drug regimens further increase the risk of adverse drug reactions and intolerance. In addition, it is necessary that certain drugs are to be avoided during pregnancy and lactation, and considerations of fetal safety are also important when treating pregnant women. It is always, therefore, necessary to have alternate drug regimens that can be used by persons that are unable to take certain medications and for pregnant and lactating women.

#### Cost of Drugs

The cost of drugs is a major limiting factor in all locations. It is assumed that local programs will use the best regimens that they can afford. In calculating the total cost of various regimens, however, it is important to consider the costs associated with less effective therapies: repeat treatment, further transmission of infection, complications, and selection for increased microbial resistance.

More effective but expensive drugs should not be reserved for referral centres. The use of less effective regimens at the primary care level quickly discourages patients from seeking the most readily and rapidly available care and fosters the transmission of infection and the risk of antimicrobial resistance developing to selected antibiotics.

#### Treatment Compliance and Acceptability of Treatment Regimen

Patient compliance with STI treatment regimens is a problem which seriously limits the effectiveness of multi-dose regimens such as those involving erythromycin and tetracyclines. Single-dose or very-short-course regimens are therefore preferred. Appropriate counselling and education have been shown to increase compliance and should be a part of clinical management.

In some societies, oral regimens are strongly preferred to injections, whereas among other groups injection may be seen as the only acceptable form of treatment. In view of the emergence and spread of HIV infection, preference should be given to oral regimens in order to reduce the risks associated with the reuse of non-sterilized injection equipment. Patient education on the efficacy of oral preparations must be included in STI management.

#### Drug Availability

The geographical distribution and availability of drugs vary considerably. The regional availability of some excellent drugs could be improved by their inclusion in the national essential drugs lists.

#### Co-existent Infections

When several STIs are prevalent in a population, co-infection may be a common occurrence. Unfortunately, the ability to treat common co-infections with single drugs has not been established widely. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are common causes of urethritis and cervicitis. It has become standard practice to treat patients with these conditions for both infections

simultaneously. Until further studies are conducted to show the efficacy of a single antimicrobial agent in treating both infections we remain with having to give two different treatment regimens for these two infections.

## TREATMENT RECOMMENDATIONS FOR SPECIFIC SEXUALLY TRANSMITTED INFECTIONS

The following paragraphs provide a summary of the current treatment recommendations for specific STIs. The recommendations have been extracted from guidelines developed by the World Health Organization, Geneva,<sup>3</sup> the Centers for Disease Control, Atlanta, US<sup>5</sup> and the European Union.<sup>6</sup> Recommendations between the different sources vary slightly but provide readers with a broader selection of antimicrobials to choose from, when developing their own National guidelines.

### Gonorrhea

#### Uncomplicated Gonorrhea

Uncomplicated gonorrhea includes gonococcal urethritis, cervicitis, pharyngitis, and proctitis in adults. Table 113.1 summarizes the recommendations for the treatment of uncomplicated gonococcal infection in men and women. Gonococcal pharyngeal infection is difficult to eradicate completely and none of the antibiotics has an efficacy of greater than 90%. The recommended treatment for gonococcal pharyngeal infection is intramuscular ceftriaxone.

**Table 113.1:** Recommendations for the Treatment of Uncomplicated Gonococcal Infection in Adult Males and Females

#### World Health Organization:

Ceftriaxone, 250 mg by intramuscular injection (IM).  
Alternatively, the following may be used:  
Cefixime, 400 mg orally (PO), Or  
Spectinomycin 2 g IM, Or  
Ciprofloxacin, 500 mg PO—to be used only in those areas where there is documented evidence of ongoing sensitivity of *N. gonorrhoeae* to quinolones.

#### Centers for Disease Control:

Ceftriaxone, 125 mg IM, Or  
Cefixime, 400 mg PO.  
Alternatively, the following may be used:  
Cefpodoxime, 400 mg PO, Or  
Cefuroxime axetil, 1 g PO, Or  
Ceftizoxime, 500 mg IM, Or  
Azithromycin, 2 g PO, Or  
Cefoxitin, 2 g IM plus probenecid 1 g PO  
Cefotaxime, 500 mg IM, Or  
Spectinomycin, 2 g IM.

#### European Guidelines

Ceftriaxone, 250 mg IM.  
Alternatively, the following may be used:  
Cefixime, 400 mg PO, Or  
Spectinomycin, 2 g IM.

Note: In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

### Gonococcal Conjunctivitis in Adults

This is a serious condition that requires systemic therapy. Infection of the conjunctiva occurs as a result of auto-inoculation of genital secretions. Education on hand washing and personal hygiene is an important component in the management of patients with this condition. Table 113.2 summarizes the treatment recommendations.

#### Neonatal Gonococcal Conjunctivitis

Neonates may become infected with *N. gonorrhoeae* at the time of birth if the mother has the infection. Gonococcal neonatal conjunctivitis, also known as gonococcal ophthalmia neonatorum, is a serious infection as it may lead to perforation of the globe and results in blindness. It is a preventable infection and ophthalmia prophylaxis should be performed routinely for all babies born to mothers living in areas where gonorrhea prevalence is significant. It may also be prevented if maternal infection is diagnosed and adequately treated before the birth of the baby. Table 113.3 summarizes the recommended treatment of neonatal gonococcal conjunctivitis.

#### Prevention of Ophthalmia Neonatorum

Gonococcal ophthalmia neonatorum is preventable with timely eye prophylaxis. WHO advises that the infant's eyes should

**Table 113.2:** Recommendations for the Treatment of Gonococcal Conjunctivitis in Adult Males and Females

#### World Health Organization:

Ceftriaxone, 250 mg IM.  
Alternatively, the following may be used:  
Spectinomycin, 2 g IM, Or  
Kanamycin, 2 g IM.

Note: Though published data are not available it is felt by experts that this treatment regimen is efficacious in treating this condition.

#### Centers for Disease Control:

Ceftriaxone, 1 g IM.  
Note: This recommendation is based on the results of one small study and on expert opinion.

Note: Local administration of antibiotic eye ointment is not recommended but irrigation the eyes with normal saline may be useful.

**Table 113.3:** Recommendations for the Treatment of Neonatal Gonococcal Conjunctivitis

#### World Health Organization:

Ceftriaxone, 50 mg/kg IM single dose (maximum dose 125 mg).  
Alternatively, the following may be used:  
Kanamycin, 25 mg/kg IM single dose (maximum dose 75 mg), Or  
Spectinomycin, 25 mg/kg IM single dose (maximum dose 75 mg).

#### Centers for Disease Control:

Ceftriaxone 25–50 mg/kg IM single dose (maximum dose 125 mg).

#### European Guidelines

Ceftriaxone 25–50 mg/kg IM single dose (maximum dose 125 mg), Or  
Cefotaxime 100 mg/kg IM single dose.

Note: Irrigation of eyes with normal saline is recommended.

be carefully cleaned immediately after birth. The application of 1% silver nitrate solution or 1% tetracycline ointment to the eyes of all infants at the time of delivery is strongly recommended as a prophylactic measure. However, ocular prophylaxis provides poor protection against *C. trachomatis* conjunctivitis. Infants born to mothers with gonococcal infection should receive: ceftriaxone, 50 mg/kg IM single dose, to a maximum of 125 mg.

Alternatively, where ceftriaxone is not available: kanamycin, 25 mg/kg IM single dose to a maximum of 75 mg or spectinomycin 25 mg/kg IM single dose to a maximum of 75 mg may be used.

### Disseminated Gonococcal Infection

Disseminated gonococcal infection results from gonococcal bacteremia. The condition causes a sparse distal pustular or petechial rash, and an asymmetric arthralgia, tenosynovitis or septic arthritis. The infection may be complicated by perihepatitis and rarely by endocarditis or meningitis. Some strains of *N. gonorrhoeae* that cause disseminated infection may produce minimal genital inflammation. Table 113.4 summarizes the treatment recommendations.

**Table 113.4:** Recommendations for the Treatment of Disseminated Gonococcal Infection

#### World Health Organization:

Ceftriaxone, 1 g IM or intravenously (IV) daily for 7 days

Alternatively, the following may be used:

Spectinomycin, 2 g IM twice daily for 7 days

*Note:* For gonococcal meningitis, treatment is continued for 14 days and for endocarditis the duration of therapy will need to be increased to 4 weeks

#### Centers for Disease Control:

Ceftriaxone, 1 g IM or intravenously (IV) daily for 7 days

Alternatively, the following may be used:

Cefotaxime, 1 g IV every 8 hours, Or

Ceftizoxime, 1 g IV every 8 hours, Or

Spectinomycin, 2 g IM twice daily

This treatment is continued for 24–48 hours after improvement begins and then the patient may be treated with cefixime, 400 mg PO daily; the total duration of antibiotics should not be less than 7 days

*Note:* For gonococcal meningitis IM or IV treatment is continued for 14 days and for endocarditis the duration of IM or IV therapy should be 4 weeks

#### European guidelines

Ceftriaxone, 1 g IM or intravenously (IV) daily for 7 days

Alternatively, the following may be used:

Cefotaxime, 1 g IV every 8 hours, Or

Spectinomycin, 2 g IM twice daily

This treatment is continued for 24–48 hours after improvement begins and then the patient may be treated with cefixime, 400 mg PO daily Or if quinolone resistance is excluded ciprofloxacin, 500 mg PO twice daily; the total duration of antibiotics should not be less than 7 days.

*Note:* For gonococcal meningitis IM or IV treatment is continued for 14 days and for endocarditis the duration of IM or IV therapy should be 4 weeks

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

## C. trachomatis Infections other than Lymphogranuloma Venereum

### Anogenital Chlamydial Infection

Anogenital chlamydial infection includes infection of the urethra, cervix, and rectum with *C. trachomatis*. Recommended regimens are shown in Table 113.5.

### Chlamydial Infection during Pregnancy

Recommendations for the treatment of chlamydial infections during pregnancy are shown in Table 113.6.

### Neonatal Chlamydial Conjunctivitis

The following are recommendations (Table 113.7) for the treatment of neonatal chlamydial conjunctivitis. It is however

**Table 113.5:** Recommendations for the Treatment of Anogenital Chlamydial Infection

#### World Health Organization:

Azithromycin, 1 g PO single dose, Or

Doxycycline, 100 mg PO 12 hourly for 7 days

Alternatively, the following may be used:

Amoxycillin, 500 mg PO 8 hourly for 7 days, Or

Erythromycin, 500 mg PO 6 hourly for 7 days, Or

Ofloxacin, 300 mg PO 12 hourly for 7 days, Or

Tetracycline, 500 mg PO 6 hourly for 7 days

#### Centers for Disease Control:

Azithromycin, 1 g PO once, Or

Doxycycline, 100 mg PO 12 hourly for 7 days

Alternatively, the following may be used:

Erythromycin base, 500 mg PO 6 hourly for 7 days, Or

Erythromycin ethylsuccinate, 800 mg PO 6 hourly for 7 days, Or

Ofloxacin, 300 mg PO 12 hourly for 7 days, Or

Levofloxacin, 500 mg PO once daily for 7 days

#### European guidelines

Azithromycin, 1 g PO once, Or

Doxycycline, 100 mg PO 12 hourly for 7 days

Alternatively, the following may be used:

Erythromycin base, 500 mg PO 6 hourly for 7 days, Or

Ofloxacin, 300 mg PO 12 hourly for 7 days

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

**Table 113.6:** Recommendations for the Treatment of Chlamydial Infection during Pregnancy

#### World Health Organization:

Erythromycin, 500 mg PO 6 hourly for 7 days, Or

Azithromycin 1 g PO single dose

Alternatively, the following may be used:

Amoxycillin, 500 mg PO 8 hourly for 7 days, Or

*Note:* In pregnant and lactating women doxycycline, tetracycline, and ofloxacin should not be used

#### Centers for Disease Control:

Azithromycin, 1 g PO once, Or

Amoxycillin, 500 mg PO 8 hourly for 7 days

Alternatively, the following may be used:

Erythromycin base, 500 mg PO 6 hourly for 7 days, Or

Erythromycin base, 250 mg PO 6 hourly for 14 days, Or

Erythromycin ethylsuccinate, 800 mg PO 6 hourly for 7 days

**Table 113.7:** Recommendations for the Treatment of Neonatal Chlamydial Conjunctivitis**World Health Organization:**

Erythromycin syrup, 50 mg/kg/day PO, in four divided doses for 14 days

Alternatively, the following may be used:

Trimethoprim, 40 mg with sulfamethoxazole, 200 mg PO, twice daily for 14 days

**Centers for Disease Control:**

Erythromycin syrup, 50 mg/kg/day PO, in four divided doses for 14 days

advisable to treat all newborn infants with conjunctivitis for both *N. gonorrhoeae* and *C. trachomatis*, because of the possibility of mixed infection.

**Infantile Chlamydial Pneumonia**

Recommendations for the treatment of chlamydial pneumonia in infants are summarized in Table 113.8.

**Syphilis**

Syphilis is a systemic infection and if untreated may lead to serious long-term complications. Syphilis may be transmitted transplacentally from an infected pregnant woman to her fetus and it may be transmitted from person to person through sexual intercourse. The infection is divided into congenital and acquired categories and within both categories there may be early and late stages. Early syphilis is defined as infection of less than 2 years duration and includes the primary, secondary, and latent stages. Late syphilis is defined as syphilis of more than 2 years duration and refers to late latent syphilis, gummatous, neurological, and cardiovascular syphilis. **Centers for Disease Control (CDC)** defines early syphilis as syphilis of less than 1 year duration and late syphilis as syphilis of more than 1 year's duration.

**Early Acquired Syphilis (Primary, Secondary, and Early Latent Syphilis)**

Table 113.9 summarizes the treatment recommendations for early acquired syphilis.

**Late Latent Acquired Syphilis (Latent Infection of >2 Year's duration or of Unknown Duration)**

Table 113.10 summarizes the recommendations for the treatment of late latent syphilis.

**Table 113.8:** Recommendations for the Treatment of Neonatal Chlamydial Pneumonia**World Health Organization:**

Erythromycin syrup, 50 mg/kg/day PO, in four divided doses for 14 days

**Centers for Disease Control:**

Erythromycin syrup, 50 mg/kg/day PO, in four divided doses for 14 days

**Table 113.9:** Recommendations for the Treatment of Early Acquired Syphilis**World Health Organization:**

Benzathine benzylpenicillin, 2.4 million IU IM, at a single session (because of the volume involved, this dose is usually given as two injections at separate sites)

Alternatively the following may be used.

Azithromycin, 2 g PO single dose, Or

Procaine benzylpenicillin, 1.2 million IU IM daily for 10 consecutive days, Or

Doxycycline, 100 mg PO 12 hourly for 14 days, Or

Tetracycline, 500 mg PO 6 hourly for 14 days

*Note:* In penicillin-allergic patients Azithromycin 2 g PO single dose is given. Alternatively erythromycin, 500 mg PO 6 hourly is given for 14 days

**Centers for Disease Control:**

Benzathine benzylpenicillin, 2.4 million IU IM, at a single session

*Note:* In penicillin-allergic patients, de-sensitization should be considered and benzathine benzylpenicillin is then given

Doxycycline, 100 mg PO 12 hourly for 14 days or tetracycline. 500

mg PO 6 hourly for 14 days may be considered

**European guidelines**

Benzathine penicillin 2.4 million units IM (1.2 million units IM into each buttock)

Alternatively, the following may be given:

Azithromycin, 2 g PO single dose, Or

Procaine benzylpenicillin, 600,000 IU IM daily for 10–14 days, Or

Doxycycline, 100 mg PO 12 hourly for 14 days, Or

Tetracycline, 500 mg PO 6 hourly for 14 days, Or

Erythromycin, 500 mg PO 6 hourly for 14 days

*Note:* In penicillin-allergic patients, Azithromycin 2 g PO single dose is given. Alternatively erythromycin, 500 mg PO 6 hourly is given for 14 days

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

**Table 113.10:** Recommendations for the Treatment of Late Latent Acquired Syphilis**World Health Organization:**

Benzathine benzylpenicillin, 2.4 million IU IM once weekly for 3 weeks

Alternatively, the following may be used:

Procaine benzylpenicillin, 1.2 million IU IM daily for 20 consecutive days, Or

*Note:* In penicillin-allergic patients use Doxycycline, 100 mg PO 12 hourly for 30 days, Or

Tetracycline, 500 mg PO 6 hourly for 30 days and in pregnant women

allergic to penicillin use erythromycin, 500 mg PO 6 hourly is given for 30 days

**Centers for Disease Control:**

Benzathine benzylpenicillin, 2.4 million IU IM once weekly for 3 weeks

*Note:* In penicillin-allergic patients, Doxycycline, 100 mg PO 12 hourly for 14 days or tetracycline 500 mg PO 6 hourly for 14 days may be given

In penicillin-allergic pregnant women, desensitization should be carried out and then the patient is treated with benzathine penicillin

**European guidelines**

Benzathine penicillin 2.4 million units IM (1.2 million units IM into each buttock)

Alternatively, the following may be given

Procaine benzylpenicillin, 600,000 IU IM daily for 17–21 days, Or

*Note:* In penicillin-allergic patients, Doxycycline, 100 mg PO 12 hourly for 21–28 days, Or

Tetracycline, 500 mg PO 6 hourly for 28 days

If the patient is a penicillin-allergic pregnant woman then give

Erythromycin, 500 mg PO 6 hourly for 28 days

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

**Late Acquired Syphilis (Gummatous and Cardiovascular Syphilis)**

The CDC guidelines for the management of gummatous syphilis and cardiovascular syphilis are shown in Table 113.11A.

**Late Acquired Neurosyphilis**

Recommendations for the management of neurosyphilis are shown in Table 113.11B. Neurologic involvement by syphilis may occur in any stage of syphilis. Once a diagnosis is made then the patient is treated for neurosyphilis as shown in Table 113.11B.

**Table 113.11A:** Recommendations for the Treatment of Late Acquired Syphilis (Gummatous and Cardiovascular Syphilis)

**Centers for Disease Control:**

Benzathine benzylpenicillin, 2.4 million IU IM once weekly for 3 weeks

*Note:* In penicillin-allergic patients Doxycycline, 100 mg PO 12 hourly for 28 days or tetracycline, 500 mg PO 6 hourly for 28 days may be given. In penicillin-allergic pregnant women desensitization should be carried out and then the patient is treated with benzathine penicillin

**Table 113.11B:** Recommendations for the Treatment of Acquired Neurosyphilis

**World Health Organization:**

Aqueous benzylpenicillin, 12–24 million IU/day by intravenous injection and administered in doses of 2–4 million IU, every 4 hours for 14 days

Alternatively, the following may be used:

Procaine benzylpenicillin, 1.2 million IU IM once daily together with Probenecid 500 mg PO four times daily, both for 10–14 days (This regimen should be used only for patients whose outpatient compliance can be assured)

*Note:* In penicillin-allergic non-pregnant patients, Doxycycline, 200 mg orally, twice daily for 30 days Or Tetracycline, 500 mg orally, four times daily for 30 days may be used.

**Centers for Disease Control:**

Aqueous benzylpenicillin, 12–24 million IU/day by intravenous injection and administered in doses of 2–4 million IU, every 4 hours for 14 days

Alternatively, the following may be used if compliance can be assured:

Procaine benzylpenicillin, 1.2 million IU IM once daily together with Probenecid 500 mg PO four times daily, both for 10–14 days

*Note:* Ceftriaxone can be used as an alternative treatment for patients with neurosyphilis, although the possibility of cross-reactivity between this agent and penicillin exists. Some specialists recommend ceftriaxone, 2 g daily either IM or IV for 10–14 days. Other regimens have not been adequately evaluated for treatment of neurosyphilis. Therefore, if concern exists regarding the safety of ceftriaxone for a patient with neurosyphilis, the patient should obtain skin testing to confirm penicillin allergy and, if necessary, be desensitized and managed in consultation with a specialist.

**European guidelines**

Aqueous benzylpenicillin, 12–24 million IU/day by intravenous injection and administered in doses of 2–4 million IU, every 4 hours for 14 days

Alternatively, the following may be used:

Procaine benzylpenicillin, 1.2 million IU IM once daily together with Probenecid, 500 mg PO four times daily, both for 10–14 days (This regimen should be used only for patients whose outpatient compliance can be assured)

*Note:* In penicillin-allergic non-pregnant patients Doxycycline, 200 mg orally, twice daily for 30 days can be used.

**Early Congenital Syphilis (up to 2 Years of Age) and Infants with Abnormal Cerebrospinal Fluid**

Recommendations for the treatment of early congenital syphilis and infants with syphilis who have an abnormal CSF are shown in Table 113.12. Effective prevention and detection of congenital syphilis depends on the identification of syphilis in pregnant women and, therefore, on the routine serologic screening of pregnant women during the first prenatal visit. In communities and populations in which the risk for congenital syphilis is high, serologic testing and a sexual history also should be obtained at 28 weeks' gestation and at delivery. Moreover, as a part of the management of pregnant women who have syphilis, information concerning treatment of sex partners should be obtained to assess the risk for reinfection.

**Congenital Syphilis of >2 Years Duration**

Table 113.13 shows the WHO guidelines on the management of congenital syphilis in children over the age of 2 years.

**Genital Herpes**

The primary cause of genital herpes is infection with the herpes simplex virus Type 2 (HSV2). This STI is highly prevalent throughout the world and has become the commonest cause of genital ulcer disease worldwide. The major public health importance of HSV2 relates to its potential role in facilitating HIV transmission. There is no known cure for genital herpes, but

**Table 113.12:** Recommendations for the Treatment of Early Congenital Syphilis

**World Health Organization:**

Aqueous benzylpenicillin 100,000–150,000 IU/kg/day administered as 50,000 IU/kg/dose IV every 12 hours, during the first 7 days of life and every 8 hours thereafter for a total of 10 days, Or Procaine benzylpenicillin, 50,000 IU/kg by intramuscular injection, as a single daily dose for 10 days

*Note:* Some experts treat all infants with congenital syphilis as if the CSF findings were abnormal. Antimicrobials other than penicillin (e.g., erythromycin) are not indicated for congenital syphilis except in cases of severe allergy to penicillin. Tetracyclines should not be used in young children.

**Centers for Disease Control:**

Aqueous crystalline penicillin G 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days, Or Procaine penicillin G 50,000 units/kg/dose IM in a single daily dose for 10 days

**Table 113.13:** Recommendations for the Management of Congenital Syphilis in Children over the Age of 2 Years

**World Health Organization:**

Aqueous benzylpenicillin, 200,000–300,000 IU/kg/day by intravenous or intramuscular injection, administered as 50,000 IU/kg every 4–6 hours for 10–14 days

Alternatively, the recommended regimen for penicillin-allergic patients, after the first month of life is erythromycin, 7.5–12.5 mg/kg orally, four times daily for 30 days

the course of symptoms can be modified if systemic therapy with anti-herpes-virus agents. Treatment with aciclovir, or its analogs, needs to be started as soon as possible following the onset of symptoms. Treatment can be expected to reduce the formation of new lesions, the duration of pain, the time required for healing, and viral shedding. Treatment, however, does not influence the natural history of recurrent disease. Treatment recommendations vary depending on the clinical stage of the infection.

### First Clinical Episode of Genital Herpes

Table 113.14 summarizes the recommendations for the treatment of the first clinical episode of genital herpes.

### Treatment of Recurrent Episodes

Treating episodes of recurrences is beneficial in that it reduces the duration of the attack and reduces the amount of viral shedding from lesions. Treatment should be commenced within 24 hours of the onset of the prodromal symptoms. The above treatments are used with the difference being that the treatment course can be shortened to 5 days. Shorter courses of these treatments may also be useful if the dose of the antiviral agent is increased: Aciclovir, 800 mg, orally twice a day for 5 days, Aciclovir, 800 mg, orally three times a day for 2 days, Famciclovir, 1000 mg, orally twice daily for 1 day, and Valacyclovir, 500 mg, orally twice a day for 3 days.

In persons with HIV infection, episodic treatment is advised as follows: Aciclovir, 400 mg, orally three times a day for 5–10 days, or Famciclovir, 500 mg, orally twice a day for 5–10 days, or Valacyclovir, 1.0 g, orally twice a day for 5–10 days.

### Suppressive Treatment

Suppressive therapy reduces the frequency of genital herpes recurrences by 70–80% in patients who have frequent recurrences (i.e., >6 recurrences/year), and many patients report no symptomatic outbreaks. Treatment also is effective in patients with less frequent recurrences. Safety and efficacy have been documented among patients receiving daily therapy with aciclovir for as long as 6 years

**Table 113.14:** Recommendations for the Treatment of the First Clinical Episode of Genital Herpes

#### World Health Organization:

Aciclovir, 200 mg orally, five times daily for 7 days, Or  
Aciclovir, 400 mg orally, three times daily for 7 days, Or  
Famciclovir, 250 mg, three times daily for 7 days, Or  
Valacyclovir, 1 g, twice daily for 7 days

#### Centers for Disease Control:

Aciclovir, 200 mg orally, five times daily for 7–10 days, Or  
Aciclovir, 400 mg orally, three times daily for 7–10 days, Or  
Famciclovir, 250 mg, three times daily for 7–10 days, Or  
Valacyclovir, 1 g, twice daily for 7–10 days

Note: Recent European guidelines on the treatment of genital herpes are not available; however, the British Association for Sexual Health and HIV (BASHH) has the same recommendations with the difference being that BASHH advises treatment for 5 days.

**Table 113.15:** Recommendations for Suppressive Therapy in Persons with Frequent Recurrences

#### World Health Organization and Centers for Disease Control:

Aciclovir, 400 mg orally, twice daily, Or  
Famciclovir, 250 mg orally, twice daily, Or  
Valacyclovir, 500 mg orally, once daily, Or  
Valacyclovir, 1000 mg orally, once daily

and with valacyclovir or famciclovir for 1 year. Quality of life frequently is improved in patients with frequent recurrences who receive suppressive therapy, compared with episodic treatment. Table 113.15 summarizes the treatment recommendations for long-term suppressive therapy for genital herpes.

Suppressive treatment may be given on a long-term basis to persons with genital herpes who are also HIV infected as follows: Aciclovir, 400–800 mg orally, twice to three times a day, or Famciclovir, 500 mg orally, twice a day, or Valacyclovir, 500 mg orally, twice a day.

In persons with severe disease, intravenous aciclovir may be used in the following doses:

Aciclovir, 5–10 mg/kg IV, every 8 hours for 5–7 days or until clinical resolution is attained.

In neonates with neonatal herpes the following is recommended: Aciclovir, 10 mg/kg intravenously, three times a day for 10–21 days.

### Trichomoniasis

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis*. Infection in women usually leads to vaginal discharge that is malodorous, profuse, and green-yellow in color and often with vulvar irritation. Some women with infection may have no symptoms. Men who are infected with *T. vaginalis* may have no symptoms or they may have a urethral discharge.

Vaginal trichomoniasis has been associated with adverse pregnancy outcomes, particularly premature rupture of membranes, preterm delivery, and low birth weight. However, data do not suggest that metronidazole treatment results in a reduction in perinatal morbidity. Although some trials suggest the possibility of increased prematurity or low birth weight after metronidazole treatment.

Table 113.16 summarizes the treatment recommendations for trichomoniasis.

### Bacterial Vaginosis

Bacterial vaginosis is the commonest cause of vaginal discharge and vaginal malodor. The condition causes the appearance of a sticky discharge, which is greyish in color. It is caused by the replacement of the normal hydrogen peroxide producing lactobacilli by high concentrations of *Gardnerella vaginalis*, *Mycoplasma hominis*, and anaerobic bacteria that include *Mobiluncus sp* and *Prevotella sp*. More than 50% of women with bacterial vaginosis are asymptomatic. Bacterial vaginosis is considered to be an endogenous reproductive tract infection and treatment of sexual partners has not been demonstrated to be of benefit. It is however associated with having

**Table 113.16:** Recommendations for the Treatment of Trichomoniasis in Men and Women**World Health Organization:**

Metronidazole, 2 g orally, in a single dose, Or  
Tinidazole, 2 g orally, in a single dose

*Alternative regimen*

Metronidazole, 400 mg or 500 mg orally, twice daily for 7 days, Or  
Tinidazole, 500 mg orally, twice daily for 5 days

*Note:* In men the 7-day regimen of metronidazole or the 5-day regimen of tinidazole is preferred.

**Centers for Disease Control:**

Metronidazole, 2 g orally, in a single dose, Or  
Tinidazole, 2 g orally, in a single dose

*Alternative Regimen*

Metronidazole, 500 mg orally, twice a day for 7 days

**European guidelines**

Metronidazole, 2 g orally, in a single dose, Or  
Metronidazole, 400–500 mg, twice daily for 5–7 days

*Alternative regimen*

Tinidazole, 2 g orally, in a single dose

multiple sex partners, a new sex partner, douching, and lack of vaginal lactobacilli. Treatment of male sex partners has not been beneficial in preventing the recurrences.

During pregnancy, bacterial vaginosis is associated with adverse pregnancy outcomes including premature rupture of the membranes, preterm labor, preterm birth, intra-amniotic infection, and post-partum endometritis. Treatment recommendations are summarized in Table 113.17.

**Candidiasis****Table 113.17:** Recommendations for the Treatment of Bacterial Vaginosis**World Health Organization recommendations:**

Metronidazole, 400 mg or 500 mg orally, twice daily for 7 days

*Alternative regimen*

Metronidazole, 2 g orally, as a single dose, Or  
Clindamycin, 2% vaginal cream, 5 g intravaginally, at bedtime for 7 days, Or

Metronidazole, 0.75% gel, 5 g intravaginally, twice daily for 5 days, Or  
Clindamycin, 300 mg orally, twice daily for 7 days

**Centers for Disease Control recommendations:**

Metronidazole, 500 mg orally, twice a day for 7 days, Or  
Metronidazole gel, 0.75%, one full applicator (5 g) intravaginally, once a day for 5 days, Or  
Clindamycin cream, 2%, one full applicator (5 g) intravaginally at bedtime for 7 days

*Alternative regimens*

Clindamycin, 300 mg orally, twice a day for 7 days, Or  
Clindamycin ovules, 100 mg intravaginally, once at bedtime for 3 days

**European guidelines**

Metronidazole, 400–500 mg twice daily for 5–7 days, Or  
Metronidazole, 2 g, single dose

*Alternative regimens*

Intravaginal metronidazole gel (0.75%) once daily for 5 days, Or  
Intravaginal clindamycin cream (2%) once daily for 7 days, Or  
Clindamycin, 300 mg, twice daily for 7 days, Or  
Tinidazole, 2 g, single dose

Vulvovaginal candidiasis usually is caused by the yeast *Candida albicans* but occasionally it is caused by other *Candida* sp. Symptoms of infection include pruritus, vaginal soreness, dyspareunia, and abnormal vaginal discharge. It is estimated that 75% of women will have at least one episode of vulvovaginal candidiasis, and 40–45% will have two or more episodes. Vulvovaginal candidiasis is usually not acquired through sexual intercourse. Although treatment of sexual partners is not recommended, partner treatment may be considered for women who have recurrent infection. A minority of male partners may have balanitis, which is characterized by erythema of the glans penis or inflammation of the glans penis and foreskin (balanoposthitis).

Treatment recommendations are summarized in Table 113.18.

**Lymphogranuloma Venereum**

Lymphogranuloma venereum (LGV) is caused by *C. trachomatis* serovars L1, L2, or L3. In heterosexual men, infection leads to a transient genital ulcer at the site of infection followed

**Table 113.18:** Recommendations for the Treatment of Vulvovaginal Candidiasis**World Health Organization:**

Miconazole or clotrimazole, 200 mg intravaginally, daily for 3 days, Or  
Clotrimazole, 500 mg intravaginally, as a single dose, Or  
Fluconazole, 150 mg orally, as a single dose

*Alternative regimen*

Nystatin, 100,000 IU intravaginally, daily for 14 days

*Note:* In men with balanitis or balanoposthitis clotrimazole 1% cream, miconazole 2% cream or nystatin cream 100,000 units/g may be applied twice daily for 7 days.

**Centers for Disease Control:**

Butoconazole, 2% cream, 5 g intravaginally for 3 days. Or  
Butoconazole, 2% cream, 5 g (Butoconazole1-sustained release), single intravaginal application, Or  
Clotrimazole, 1% cream, 5 g intravaginally for 7–14 days, Or  
Clotrimazole, 100 mg, vaginal tablet for 7 days, Or  
Clotrimazole, 100 mg, vaginal tablet, two tablets for 3 days, Or  
Miconazole, 2% cream, 5 g intravaginally for 7 days  
Miconazole, 100 mg, vaginal suppository, one suppository for 7 days, Or  
Miconazole, 200 mg vaginal suppository, one suppository for 3 days, Or  
Miconazole, 1200 mg, vaginal suppository, one suppository for 1 day, Or  
Nystatin, 100,000-unit vaginal tablet, one tablet for 14 days, Or  
Tioconazole, 6.5% ointment, 5 g intravaginally in a single application, Or  
Terconazole, 0.4% cream, 5 g intravaginally for 7 days, Or  
Terconazole, 0.8% cream, 5 g intravaginally for 3 days, Or  
Terconazole, 80 mg, vaginal suppository, one suppository for 3 days

*Oral Agent:*

Fluconazole, 150 mg oral tablet, one tablet in single dose

**European guidelines**

*Induction:* Fluconazole capsule, 150 mg, every 72 hours × 3 doses  
*Maintenance:* Fluconazole capsule, 150 mg, once a week for 6 months

*Alternative Regimens*

*Induction:* Topical imidazole therapy can be increased to 10–14 days according to symptomatic response

*Maintenance:* Clotrimazole pessary, 500 mg, once a week for 6 months

Fluconazole capsule, 50 mg, daily for 6 months  
Itraconazole capsule, 50–100 mg, daily for 6 months  
Ketoconazole capsule, 100 mg, daily for 6 months

**Table 113.19:** Recommendations for the Treatment of Lymphogranuloma Venereum Infection**World Health Organization:**

Doxycycline, 100 mg orally, twice daily for 14 days, Or  
Erythromycin, 500 mg orally, four times daily for 14 days

*Alternative regimen*

Tetracycline, 500 mg orally, four times daily for 14 days

*Note:* Fluctuant lymph nodes (buboes) containing pus should be aspirated through healthy skin. Incision and drainage or excision of nodes may delay healing. Some patients with advanced disease may require treatment for longer than 14 days, and sequelae such as strictures and/or fistulae may require surgery.

**Centers for Disease Control:**

Doxycycline, 100 mg orally, twice a day for 21 days

*Alternative Regimen*

Erythromycin base, 500 mg orally, four times a day for 21 days

**European guidelines**

Doxycycline, 100 mg twice, daily orally for 21 days (or tetracycline 2 g daily Or  
Minocycline, 300 mg, loading dose followed by 200 mg twice daily Or  
Erythromycin, 500 mg, four times daily orally for 21 days.)

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

by the development of inguinal and femoral lymphadenitis. Suppuration and abscess formation may occur in affected lymph nodes. Rectal exposure in women or men who have sex with men may lead to proctocolitis. Table 113.19 summarizes the treatment recommendations for LGV.

**Granuloma Inguinale (Donovanosis)**

Granuloma inguinale (Donovanosis) is a genital ulcerative disease caused by the intracellular gram-negative bacterium *Klebsiella granulomatis*. Clinically, patients with donovanosis present with progressive painless genital ulcers usually starting with the appearance of a nodule at the site of infection. Ulcers develop at the site of the nodules. Ulcers are vascular, bleed easily on contact and are beefy-red in appearance. Regional lymph node enlargement typically does not occur. Recommendations for treatment are shown in Table 113.20.

**Chancroid**

Chancroid is caused by *Haemophilus ducreyi*, a gram-negative bacterium that is sexually transmitted. After a short incubation period patients develop painful ulcers at the site of infection and regional lymphadenitis. Suppuration with abscess formation develops in the affected acutely inflamed lymph nodes. Table 113.21 summarizes the treatment recommendations for chancroid.

**Genital Warts**

Genital warts are caused by the human papilloma virus (HPV). They appear as flat, papular or pedunculated growths on the genital area. HPV types 6 or 11 are the common causes of visible warts. However other strains of HPV, high-risk strains that include types 16, 18, 31, 33, and 35, cause cervical carcinoma. In addition

**Table 113.20:** Recommendations for the Treatment of Granuloma Inguinale (Donovanosis)**World Health Organization:**

Azithromycin, 1 g orally on first day, then 500 mg orally, once a day, Or

Doxycycline, 100 mg orally, twice daily

*Alternative regimen*

Erythromycin, 500 mg orally, four times daily, Or

Tetracycline, 500 mg orally, four times daily, Or

Trimethoprim 80 mg/sulfamethoxazole 400 mg, two tablets orally, twice daily for a minimum of 14 days

*Note:* Treatment should be continued until ulcers have healed completely.

**Centers for Disease Control:**

Doxycycline, 100 mg orally, twice a day for at least 3 weeks and until all lesions have completely healed

*Alternative Regimens*

Azithromycin, 1 g orally, once/week, Or

Ciprofloxacin, 750 mg orally, twice a day, Or

Erythromycin base, 500 mg orally, four times a day, Or

Trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day

*Note:* Treatment should be continued for at least 3 weeks and until ulcers have healed completely.

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

**Table 113.21:** Recommendations for the Treatment of Chancroid**World Health Organization:**

Ciprofloxacin, 500 mg orally, twice daily for 3 days, Or

Erythromycin, 500 mg orally, four times a day for 7 days, Or

Azithromycin, 1 g orally, as a single oral dose

*Alternative regimen*

Ceftriaxone, 250 mg IM, as a single dose

*Note:* No local treatment is needed for lesions—patients should be advised to keep the lesions clean by frequent washing. Fluctuant lymph nodes with pus in them should be aspirated with a needle.

**Centers for Disease Control:**

Azithromycin, 1 g orally, in a single dose, Or

Ceftriaxone, 250 mg intramuscularly (IM) in a single dose, Or

Ciprofloxacin, 500 mg orally, twice a day for 3 days, Or

Erythromycin base, 500 mg orally, three times a day for 7 days

*Note:* Ciprofloxacin is contraindicated for pregnant and lactating women.

*Note:* In pregnant and lactating women, doxycycline, tetracycline, and fluoroquinolones should not be used.

to appearing on the external genitalia, i.e., penis, vulva, scrotum, perineum, and peri-anal skin, genital warts can also occur on the uterine cervix, vagina, urethra, anus, and mouth. Vaccines are available for the prevention of some of the high-risk strains of HPV.

Visible genital warts are treated by physical or chemical removal. Recommendations for treatment are summarized in Table 113.22.

**Scabies**

Scabies is caused by the mite *Sarcoptes scabiei*. Infection is transmitted by direct body contact. In adults this is often

**Table 113.22:** Recommendations for the Treatment of Genital Warts**World Health Organization:***Patient-applied*

Podofilox, 0.5% solution or gel, twice daily for 3 days, followed by 4 days of no treatment, the cycle repeated up to four times (total volume of podofilox should not exceed 0.5 ml/day), Or

Imiquimod, 5% cream applied with a finger at bedtime, left on overnight, three times a week for as long as 16 weeks; wash off 6–10 hr after application

*Note:* The safety of both podofilox and imiquimod during pregnancy has not been established.

*Provider-administered*

Podophyllin, 10–25% in compound tincture of benzoin, applied carefully to the warts once a week; wash off 1–4 hours after each application, Or

Trichloroacetic acid (TCA), 80–90%, applied carefully to the warts each week, avoiding normal tissue, followed by powdering of the treated area with talc or sodium bicarbonate (baking soda) to remove unreacted acid. Repeat application at weekly intervals

*Note:* Some experts advise against the use of podophyllin for anal warts. Large amounts of podophyllin should not be used because it is toxic and easily absorbed. Its use during pregnancy and lactation is contraindicated.

Cryotherapy with liquid nitrogen, solid carbon dioxide, or a cryoprobe, apply every 1–2 weeks, Or  
electrosurgery (electrocautery), Or  
surgical removal

**VAGINAL WARTS**

Cryotherapy with liquid nitrogen, Or

Podophyllin, 10–25%. Allow to dry before removing speculum, Or

Trichloroacetic acid (TCA), 80–90%, applied carefully to the warts each week

**CERVICAL WARTS**

Treatment of cervical warts should not be started until the results from a cervical smear test are known. Most experts advise against the use of podophyllin or TCA for cervical warts—treat patients with cryotherapy, electrocautery, or surgery.

**MEATAL AND URETHRAL WARTS**

Accessible meatal warts may be treated with podophyllin 10–25%, Or podophyllotoxin 0.5%, Or electrosurgical removal

**Centers for Disease Control:***Patient-applied:*

Podofilox 0.5% solution or gel. Patients should apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. This cycle may be repeated, as necessary, for up to four cycles. Or

Imiquimod 5% cream applied once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6–10 hours after the application.

*Note:* The safety of podofilox and imiquimod during pregnancy has not been established.

*Provider-administered:*

Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1–2 weeks, Or

Podophyllin resin, 10–25%, in a compound tincture of benzoin, applied weekly

*Note:* Do not use if skin is broken and wash off 1–4 hours after applying. The safety of podophyllin in pregnancy is not established. Or

Trichloroacetic acid (TCA) or Bichloroacetic acid (BCA) 80–90%—applied only to the warts and allowed to dry. If an excess amount of acid is applied, the treated area should be powderd with talc, sodium bicarbonate (i.e., baking soda), or liquid soap preparations to remove unreacted acid. This treatment can be repeated weekly, if necessary. Or

Surgical removal either by tangential scissor excision, tangential shave excision, curettage, or electrosurgery

*Alternative Regimens*

Intralesional interferon Or Laser surgery.

through sexual contact, but there are situations in which scabies is transmitted through close body contact not related to sexual activities, such as overcrowded homes and institutions, and bed sharing. For outbreaks of scabies related to non-sexual contact, treatment of all people living in the household or institution is critical. In persons who may have acquired the infestation through sex then sexual partners should also be treated. Adult mites can burrow into the skin within 1 hour. A hypersensitivity reaction develops and this leads to the characteristic symptom of pruritus (itch), usually 2–6 weeks after initial infestation. In reinfestations, the itch may start up soon after infestation occurs.

Pruritus sometimes persists for several weeks after adequate therapy. A single repeat treatment after 1 week may be appropriate if there is no clinical improvement. Additional weekly treatments are warranted only if live mites can be demonstrated. Clothing or bed linen that has possibly been contaminated by the patient in the 2 days prior to the start of treatment should be washed and dried. Treatment recommendations are summarized in Table 113.23.

**Table 113.23:** Recommendations for the Treatment of Scabies**World Health Organization:***Treatment of scabies in adults, adolescents and older children*

Lindane, 1% lotion or cream, applied thinly to all areas of the body from the neck down and washed off thoroughly after 8 hours, Or  
Permethrin cream, 5%, Or

Benzyl benzoate, 25% lotion, applied to the entire body from the neck down, nightly for 2 nights; patients may bathe before reapplying the drug and should bathe 24 hours after the final application, Or  
Crotamiton, 10% lotion, applied to the entire body from the neck down nightly for 2 nights and washed off thoroughly 24 hours after the second application; an extension to 5 nights is necessary in some, Or  
Sulfur, 6% in petrolatum, applied to the entire body from the neck down nightly for 3 nights; patients may bathe before reapplying the product and should bathe 24 hours after the final application.

*Note:* Lindane is not recommended for pregnant or lactating women.

*Treatment of scabies in infants, children under 10 years of age, pregnant or lactating women*

Crotamiton, 10%, as above, Or  
Sulfur, 6%, as above, Or  
Permethrin, 5% cream, applied in the same way as the sulfur regimen described above.

*Note:* Sexual contacts and all household contacts should be treated as above.

**Centers for Disease Control:**

Permethrin cream (5%) applied to all areas of the body and washed off after 8–14 hours, Or

Ivermectin 200 µg/kg orally, repeated in 2 weeks

*Alternative Regimens*

Lindane (1%) 1 oz. of lotion or 30 g of cream applied in a thin layer to all areas of the body from the neck down and thoroughly washed off after 8 hours

*Note:* Infants, young children, and pregnant or lactating women should not be treated with lindane. They can be treated with permethrin. Ivermectin is not recommended for pregnant or lactating patients. The safety of ivermectin in children who weigh <15 kg has not been determined.

## Phthiriasis (Pediculosis Pubis; Pubic Lice)

The louse, *Pthirus pubis*, is the cause of pediculosis pubis (pubic lice). The infestation is usually transmitted by sexual contact. Patients usually seek medical care because of pruritus. Treatment recommendations are summarized in Table 113.24.

**Table 113.24:** Recommendations for the Treatment of Phthiriasis (Pediculosis Pubis; Pubic Lice)

### World Health Organization:

#### Recommended regimens

Lindane, 1% lotion or cream, rubbed gently but thoroughly into the infested area and adjacent hairy areas and washed off after 8 hours; as an alternative, lindane 1% shampoo, applied for 4 minutes and then thoroughly washed off, Or

Pyrethrins plus piperonyl butoxide, applied to the infested and adjacent hairy areas and washed off after 10 minutes; retreatment is indicated after 7 days if lice are found or nits are observed at the hair-skin junction. Clothing or bed linen that may have been contaminated by the patient in the 2 days prior to the start of treatment should be washed and dried well, or dry-cleaned, Or  
Permethrin 1%, as above

*Note:* Lindane is not recommended for pregnant or lactating women.

### Centers for Disease Control:

Permethrin, 1% cream rinse applied to affected areas and washed off after 10 minutes, Or

Pyrethrins with piperonyl butoxide applied to the affected area and washed off after 10 minutes

#### Alternative Regimens

Malathion, 0.5%, lotion applied for 8–12 hours and washed off, Or  
Ivermectin, 250 µg/kg, repeated in 2 weeks

## Summary

The importance of establishing standardized guidelines for the management of STIs nationally cannot be over-emphasized. The development of such guidelines requires inputs from laboratory specialists, epidemiologists, national essential drug programs as well as clinicians and pharmacists.

When selecting appropriate drugs for the treatment of STIs consideration should be given to the efficacy of the recommended drugs, and their safety and ease of administration. The cost of drugs is also an important consideration especially in resource constrained settings. However, it is probably more cost effective to use more costly drugs that are more effective at the first point of contact a patient makes with a health facility than using cheaper drugs that are less effective as treatment failures result in further transmission of infection, and increase the risk of the development of complications of infection and in selecting drug-resistant strains of pathogens.

In this chapter, a review of recommendations made by the World Health Organization, the Centers for Disease Control, and the European Union is provided.

# Guidelines for the Treatment of HIV in Industrialized and Middle Income Countries—Adults, Adolescents, and Pediatric

Saliya Hewagama • Jennifer Hoy

# 114

To date, a cure for HIV has remained elusive, largely due to the inability to eradicate latent infection of host reservoirs of CD4 cells early in the course of disease.<sup>1</sup> Antiretroviral therapy, therefore, is primarily aimed at maximum suppression of viral replication, which has been shown to prevent progression to AIDS and reduce morbidity and mortality by restoring immunological function.<sup>2,3</sup> The use of combination antiretroviral therapy is associated with durable virological suppression, which also limits the emergence of resistant viral strains.

Viral suppression also serves to curb the HIV epidemic by reducing transmission and increasingly the benefits of viral suppression on “non-AIDS” events have become apparent. The Strategies for Management of Antiretroviral Therapy (SMART) group performed a randomized trial of 5472 participants whose baseline CD4 count was greater than 350 cells/mm<sup>3</sup>.<sup>4</sup> Patients were assigned to “drug conservation” (DC)—use of antiretroviral therapy (ART) only when their CD4 count was less than 250 cells/μL and continued until the count rose above 350 cells/μL, when it was stopped again; or to “virological suppression” (VS) where the ART was uninterrupted once initiated. Perhaps not surprisingly, the DC group had a significantly increased risk of opportunistic disease or all cause mortality (HR 2.6, 95% CI 1.9–3.7;  $p < 0.001$ ) but only 8% of deaths were due to opportunistic disease and unexpectedly, the DC group had more cardiovascular, renal, and hepatic disease (HR 1.7, 95% CI 1.1–2.5;  $p = 0.009$ ) despite being exposed to less ART, which had previously been thought to be a major contributor to these “non-AIDS” events.

This landmark trial has provided clear evidence that once started, ART should generally be continued indefinitely as the risks of uncontrolled HIV viremia outweigh the potential risks of drug toxicity.<sup>5</sup> With the emphasis on lifelong treatment now, the decision of when to start ART has become even more important.

## When to Treat?

### ASYMPTOMATIC PATIENTS

The era of antiretroviral therapy began in 1987 with the introduction of the first nucleoside reverse transcriptase inhibitor (NRTI), zidovudine (AZT) that was used initially to treat patients with severe immunosuppression (CD4 counts less than 200 cells/μL) or opportunistic illness.<sup>6</sup> It soon became apparent that the use of zidovudine monotherapy in patients, not at immediate risk of disease progression or death, was not beneficial in the long term<sup>7–11</sup> with the rapid development of resistance and lack of any survival benefit. Dual NRTI therapy with AZT and didanosine (ddI) or zalcitabine (ddC) followed,<sup>9,12,13</sup> but still quickly selected for resistant viral strains.<sup>14,15</sup>

The introduction of highly active antiretroviral therapy (HAART or more simply cART) in 1996 revolutionized the management of HIV.<sup>3,16</sup> Combination ART (cART) involves the use of three antiretroviral drugs from at least two different classes and was shown to effectively provide durable virological suppression and the development of protease inhibitors in 1995 appeared to confer an additional benefit on survival when used as part of cART<sup>2,3,10,16</sup> likely attributable to their potency and high barrier to resistance when ritonavir boosted.<sup>17</sup>

It became evident that the initial hope of viral eradication was not attainable due to infection of latent T-cell reservoirs,<sup>18,19</sup> but virological suppression was demonstrated to have many other benefits—allowing restoration of the T-cell count and immune responses against infections such as *Pneumocystis jirovecii* (PCP), *Mycobacterium avium* complex (MAC), and cytomegalovirus (CMV). This translated into dramatically improved survival and reduced incidence of opportunistic infections and AIDS events.<sup>2,3</sup>

Despite the success of cART, there were negative aspects to treatment. Pill burden in the early years of antiretroviral therapy was a major hindrance with some regimens requiring patients

to take 6–8 tablets three times per day. Side effects were also considerable ranging from severe diarrhoea or skin rash, to long-term side effects of lipodystrophy, diabetes, and peripheral neuropathy. Compliance and medication toxicity became the major issues facing HIV management and with the limited number of drug options, it was clear that a treatment threshold had to be established.

In patients not yet on cART, a higher HIV viral load is associated with more rapid HIV disease progression independent of CD4 cell count.<sup>20,21</sup> However, in patients commencing cART, CD4 cell count is more important than HIV viral load in determining the need for treatment.<sup>22</sup> The risk of AIDS events and death clearly increases with falling CD4 cell count.<sup>23,24</sup> A number of randomized trials have demonstrated that there is a clear benefit to ART below a CD4 count of 200 cells/ $\mu$ L.<sup>25–27</sup> Opportunistic infections, non-AIDS events, and death are all reduced substantially with initiation below this CD4 count level.<sup>22,28</sup> A number of large observational cohort studies have also shown similar benefits.<sup>29,30</sup>

There is also some evidence for the benefit of ART above a CD4 count of 200 cells/ $\mu$ L. A study of 816 HIV-positive patients with CD4 counts of between 200 and 350 cells/ $\mu$ L was undertaken in Haiti. Participants were randomized to an open label trial of ART within 2 weeks, compared with standard of care, waiting for a CD4 count less than 200 cells/ $\mu$ L or symptomatic illness.<sup>31</sup> The study showed a higher mortality (HR 4.0,  $p = 0.001$ ) and high incidence of tuberculosis (HR 2.0,  $p = 0.01$ ) if ART was delayed until a CD4 count of 200 cells/ $\mu$ L or less, although this study was perhaps not directly comparable to first world nations.

Controversy currently exists now over the benefits of treatment initiation above 500 cells/ $\mu$ L. There are a number of arguments in favor of earlier treatment. It has been suggested that an individual's CD4 response to cART may be linked to their nadir CD4 count,<sup>32,33</sup> hence earlier antiretroviral treatment would allow patients to sustain far greater periods of good immune function than if therapy had been delayed.<sup>34</sup> There have been some conflicting studies with regards to this theory<sup>35</sup> and it remains unproven if earlier cART would provide a benefit in this regard. Non-AIDS events such as cardiovascular disease, liver disease, and malignancies may be associated with HIV viral replication<sup>36–39</sup> and certainly the SMART study demonstrated a lower rate of cardiovascular events in the group on continuous ART when compared with patients interrupting therapy.<sup>4</sup> From a public health perspective, earlier treatment of HIV may limit the transmission of the virus and act to curb the rate of new infections.<sup>16,40</sup>

The current debate centres around evidence from the analysis of two retrospective cohort studies—the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD) study<sup>41</sup> and the Antiretroviral Therapy Cohort Collaboration (ARTCC)<sup>30</sup> that have provided somewhat different results.

The NA-ACCORD study<sup>41</sup> performed two parallel analyses across their cohort; the first of which compared the rates of all cause mortality in patients initiating ART for the first time with

a CD4 count of 351–500 cells/ $\mu$ L to those with a CD4 count 350 cells/ $\mu$ L or less. Of 8362 patients, 25% initiated ART within the CD4 range of interest and were found to have a relative risk of death of 1.69 (95% CI 1.25–2.26;  $p < 0.001$ ). This risk reduced slightly when adjusted for intravenous drug use among patients and became non-significant statistically (RR 1.28; 95% CI 0.85–1.93;  $p = 0.23$ ). The second analysis was performed in patients starting ART with a CD4 count of greater than 500 cells/ $\mu$ L compared with those starting below this level. A total of 9155 patients were used in this analysis, of which 24% started ART at a CD4 count above 500 cells/ $\mu$ L. A relative risk of death of 1.94 (95% CI 1.37–2.79;  $p = 0.006$ ) was seen in the group who deferred initiation of ART and the risk remained similar when accounting for intravenous drug use (RR 2.00; 95% CI 1.15–3.46;  $p = 0.001$ ) in this analysis. Unsurprisingly, where cause of death was identified, the majority of deaths were due to non-AIDS events in both analyses.

The ARTCC study evaluated the combined endpoint of AIDS events and death from any cause in over 45,000 patients from North America and Europe from both before and after the introduction of cART. Deferring treatment until a CD4 count of 251–350 cells/ $\mu$ L, as compared with commencing at a CD4 of 351–450 cells/ $\mu$ L, was associated with an increased risk of AIDS (HR 1.28, 95% CI 1.04–1.57). In contrast to the NA-ACCORD data, at CD4 count ranges greater than 450 cells/ $\mu$ L the hazard ratios benefit of initiating cART became statistically non-significant.

While both studies appear to show benefits of earlier antiretroviral therapy, albeit at somewhat differing thresholds, these increased relative risks translate into only a small number of actual events. Neither study looked at non-fatal non-AIDS events that are likely to be more common than AIDS events at higher CD4 counts<sup>27,42</sup>—although there is some evidence that these too may be reduced by treatment of HIV.<sup>4,39</sup> Both studies used sophisticated statistical methods to try and adjust for confounders, including intravenous drug use and lead time bias, but inevitably residual confounders will persist and will remain a major limitation to the interpretation of their results.

To date the only randomized data for the benefit of earlier ART in patients with CD4 counts greater than 350 cells/ $\mu$ L exists in the form of a subset analysis of the Strategies for Management of Antiretroviral Therapy (SMART) study comprising of 477 patients off ART at enrolment into the study (52% were ART naive).<sup>43</sup> Within the confines of this post-hoc analysis, delaying ART until CD4 counts fell below less than 250 cells/ $\mu$ L, was associated with an increased risk of AIDS or death (HR 3.47, 95% CI 1.26–9.56,  $p = 0.02$ ) and non-AIDS events (HR 7.02, 95% CI 1.57–31.38) when compared with starting above a CD4 count of 350 cells/ $\mu$ L. These patients, however, were not randomized with the intent of what CD4 threshold to start ART and as such this study does not truly answer the original question. Ultimately a randomized controlled trial is required to answer this question. The Strategic Timing of Antiretroviral Treatment (START) trial is enrolling patients with a CD4 count above 500

cells/ $\mu$ L and randomizing them to begin ART immediately or defer until the CD4 count has fallen to 350 cells/ $\mu$ L. This study will provide some of the best evidence for the timing of ART initiation; however, the completion of the trial, and therefore the trial results, will likely be some years away.

Unsurprisingly given this debate, current guidelines across the world differ in their recommendations as to the optimal timing of ART. The US DHHS panel<sup>44</sup> agreed strongly that ART should be given at CD4 counts less than 350 cells/ $\mu$ L but also recommend treatment at counts between 350 and 500 cells/ $\mu$ L, although the panel was split on the strength of this recommendation. Above 500 CD4 cells the panel was again divided in opinion with 50% recommending ART and 50% considering it optional. Despite this the San Francisco HIV treatment policy is now one of “test and treat”<sup>45</sup> and only time will tell if this decision was justified or perhaps premature. The European Clinical AIDS Society (EACS) antiretroviral treatment guidelines<sup>46</sup> are similar to the DHHS in their guidelines for CD4 counts below 350 cells/ $\mu$ L. Between 350 and 500 CD4 cells, treatment is recommended in those with hepatitis co-infection, high cardiovascular risk, malignancy, high viral load or rapid CD4 decline and in women who are pregnant. They do not however recommend ART at CD4 levels greater than 500 cells/ $\mu$ L.

In light of such controversy, and while awaiting the results of the START trial, the decision to start ART in an asymptomatic patient with a CD4 count of greater than 350 cells/ $\mu$ L is very much one that needs to be made on an individual patient basis. Given the results provided by the SMART study,<sup>4</sup> definitively demonstrating that once started, continuous ART without interruption reduces mortality and, unexpectedly, non-AIDS events—the decision to start a patient on ART is not one to be taken lightly. Important considerations must include the need for compliance to prevent development of viral resistance, drug toxicities, quality of life, pill burden, and also medical comorbidities such as hepatitis co-infection and pregnancy (see below). Costs, both to patient and healthcare system also need to be factored. Ultimately, an informed discussion with each individual patient regarding the benefits and risks of early ART is needed.

## ACUTE OPPORTUNISTIC INFECTION

Opportunistic infections (OI) occur at states of profound immunosuppression so it would seem logical that ART would be beneficial in this setting. Where no or limited effective medical therapy exists other than presence of an intact immune system this is certainly the case, for example progressive multifocal leukoencephalopathy (PML), cryptosporidiosis, and microsporidiosis.<sup>47–49</sup> However, in the setting of an acute OI with effective medical treatment the timing of ART initiation may vary.

ART leads to recovery of the host immune system and pathogen-specific immunological responses thereby improving treatment efficacy of the original OI while also acting to prevent further OIs from developing. However, concerns that severely

ill patients may not tolerate ART in the setting of acute illness and the potential for drug interactions and overlapping toxicities detrimental to the patient have resulted in delayed initiation of ART in this setting. Immune reconstitution inflammatory syndrome (IRIS) is also a common concern,<sup>28,50</sup> and may actually cause clinical deterioration and it is for this reason some experts recommend delaying ART initiation until the completion of the OI therapy.

For some OIs, such as PCP, the benefits of early ART are clear. Zolopa et al.<sup>28</sup> randomized 282 patients with a variety of OIs to “early ART”, defined as treatment within 14 days of diagnosis (median 12 days), versus “deferred ART”, defined as after completion of treatment for the OI (median 45 days) (ACTG 5164). The predominant OIs in the study were *Pneumocystis jirovecii* pneumonia (63%) with cryptococcal meningitis (12%) the next most common diagnosis. The early ART group had fewer AIDS progression/deaths (OR 0.51, 95% CI 0.27–0.94) and longer time to progression to AIDS or death (HR 0.53; 95% CI 0.30–0.92). IRIS occurred in 7.6% of patients at a median of 33 days on ART, and there was no difference in rates of IRIS whether treatment was started late or early. The use of corticosteroids (in 70% of patients with PCP) delayed but did not prevent the occurrence of IRIS. Previous concerns regarding an increased rate of adverse effects from overlapping medication toxicity were not seen in the study.

Timing of ART initiation in other OIs is less clear. With regards to pulmonary tuberculosis and HIV, the SAPIT study<sup>51</sup> from South Africa examined over 600 patients with new diagnosis of both pulmonary tuberculosis and HIV and randomized them to one of three treatment arms. The first group were started on ART at the completion of tuberculosis treatment (sequential therapy), the remaining two groups received their HIV treatment during their tuberculosis treatment (integrated therapy)—either early (within 4 weeks) or late (within 4 weeks of the completion phase of the intensive phase of tuberculosis treatment—i.e., at 2 months). The combined integrated therapy arms, when compared against the sequential group, were clearly associated with a lower mortality rate (5.4 per 100 person years versus 12.1 per 100 person years; HR 0.44; 95% CI 0.25–0.79,  $p=0.003$ ) with no difference in the rate of adverse events although IRIS was more common in the integrated treatment group. This result led to early termination of the sequential arm by the data safety monitoring board (DSMB) and the study continued with only the two integrated groups.

Thirty-five patients with cryptococcal meningitis (CM) were included in the ACTG 5164 study described above, and there was no difference in the incidence of IRIS or mortality,<sup>28</sup> but a more recent prospective randomized study suggested that ART given very early in the treatment course of cryptococcal meningitis may in fact be detrimental. A Zimbabwean study of CM<sup>52</sup> randomized 54 patients to either “early ART” (within 72 hours) or “delayed ART” (after 10 weeks of fluconazole therapy). These patients were severely immunocompromised with a median CD4 count of 37 cells/ $\mu$ L; however, the 3 year mortality rate

was significantly better in the delayed ART group (88% vs. 54%,  $p < 0.006$ ) equating to almost a three times greater risk of death with early ART. The majority of these deaths were due to CM itself and occurred within 4 weeks of starting treatment suggesting that IRIS may have had a significant contribution.

Other retrospective studies of ART initiation in tuberculosis<sup>53</sup> and severe PCP<sup>54</sup> also show a clear survival benefit of early ART although once again there is no consensus as to the exact timing. The overall evidence is that for patients with acute OIs for which medical treatment exists should receive early ART, starting during the treatment of their OI, but exactly how early is a question that remains unanswered.<sup>49</sup> In the absence of controlled evidence it seems prudent to establish the patient on primary treatment for their OI ensuring they tolerate this and do not suffer adverse effects, and then start ART soon after<sup>49</sup>—perhaps earlier in PCP than in CM where the consequences of IRIS can be more devastating.

## Individual Drugs and Side Effects

The number of antiretroviral drugs has expanded rapidly since their advent in 1987, starting with a couple of drugs within a single class, to the current state in 2010 of 15 drugs across six different classes. ART development has been unique in that different classes of agents which have been developed to target specific processes within the HIV lifecycle (see Chapter 66, “Human Immunodeficiency Virus: Biology and Natural History of Infection”), such that combination therapy involving at least two different classes limits the development of resistance.<sup>2,3,10,16</sup>

### NUCLEOSIDE/NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

The first class of ART developed was the nucleoside reverse transcriptase inhibitors (NRTIs) and began with the introduction of zidovudine (AZT) in 1987.<sup>55</sup> NRTIs competitively inhibit the viral reverse transcriptase enzyme (RNA-dependent DNA polymerase) that facilitates viral RNA transcription into a complete DNA molecule. As nucleoside/nucleotide analogs, they are incorporated by reverse transcriptase into the newly formed DNA but prevent chain elongation thereafter, thereby terminating the process. They include nucleoside analogs—zidovudine (AZT), didanosine (ddI), stavudine (d4T), lamivudine (3TC), emtricitabine (FTC), zalcitabine (ddC), and abacavir (ABC)—or the single nucleotide analogue—tenofovir (TDF). In addition to HIV DNA polymerase, humans also have a number of their own DNA polymerases, specifically  $\beta$  and  $\gamma$ , which are also inhibited by NRTIs and interfere with ATP and mitochondrial enzyme production, leading to mitochondrial toxicity and increased lactate production. Clinically, this can manifest as myopathy, peripheral neuropathy, pancreatitis, and lactic acidosis.

Peripheral neuropathy associated with NRTIs is particularly seen with the older agents in the class—stavudine, zalcitabine, and didanosine—in up to 30% of patients treated with these agents.<sup>56</sup> Classically, the neuropathy presents relatively acutely with a painful, distal, sensory neuropathy that may improve

after drug cessation, albeit sometimes after a brief progression of symptoms.<sup>57</sup> Unlike HIV-associated peripheral neuropathy, NRTI-associated neuropathy often occurs in the setting of suppressed viral replication. Given the frequency of this complication developing, these NRTIs are now rarely used in the modern cART era.

Lipodystrophy, first described in 1998,<sup>58</sup> is a condition seen commonly in HIV and while it can be seen in antiretroviral naive patients, it is more often seen as a complication of cART.<sup>59</sup> While there is no formal consensus definition, it encompasses both peripheral lipodystrophy (loss of fat on limbs and face) associated with NRTI and NNRTI (specifically efavirenz) use,<sup>60,61</sup> and central lipohypertrophy (central obesity, visceral fat, and buffalo humps) often seen with protease inhibitor (PI) use.<sup>62</sup> Patients frequently have associated metabolic derangement including insulin resistance and dyslipidemia with resultant increase in cardiovascular risk.<sup>62</sup> Within the NRTI class, the thymidine analogs (zidovudine and stavudine) have the greatest association with lipodystrophy and tenofovir, abacavir and lamivudine the least.<sup>62</sup> However it is the cosmetic consequences that can be extremely distressing to patients, compounded by the lack of effective treatment options available for this condition. Changing the offending antiretroviral to another agent leads to some improvement in subcutaneous fat mass,<sup>63–65</sup> but in general, fat changes are slow to improve and cosmetic surgery may provide some benefit.<sup>60</sup>

Some specific drug side effects are listed in Table 114.1. Of particular note, abacavir has the potential to cause a serious hypersensitivity reaction, classically occurring after approximately 1–2 weeks of treatment and presenting with fever, rash, and abnormal liver function. This reaction could be potentially fatal, especially on re-exposure to ABC. In 2008, the HLA B57\*01 genotype, found in 5.6% of a study population, was found to significantly predict immunologically confirmed reactions with a negative predictive value of 100% and a positive predictive value of 47.9%.<sup>66</sup> This test is now considered mandatory prior to consideration of ABC use in treatment guidelines.<sup>44,67</sup>

### NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

As the name suggests, non-nucleoside reverse transcriptase inhibitors (NNRTIs) also inhibit viral reverse transcriptase, but they do so by actually interfering with the enzyme's activity rather than by being incorporated into the viral DNA particle. They are divided into the first generation NNRTIs—delavirdine, which is rarely used in modern practice, nevirapine (NVP), and efavirenz (EFV)—and the newer second generation NNRTIs—etravirine (ETV) and rilpivirine (TMC278).

Class side effects of the NNRTIs include rash, which is relatively common with all members of the NNRTI group although there is only minor cross-reactivity between the individual drugs, i.e., rash to one agent does not predict the development of rash with another NNRTI (Table 114.2). All drugs in this class are metabolized by cytochrome P450 3A4 enzymes and variably induce or inhibit the same enzymes making drug interactions an important consideration

**Table 114.1:** Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

NRTI	Dosing	Common side effects	Less common side effects	Other features
Zidovudine (AZT)	250 mg BD	Bone marrow suppression—esp. anemia Gastrointestinal upset Lipoatrophy	Lactic acidosis Myopathy	Prevention of mother-to-child transmission
Lamivudine (3TC)	150 mg BD OR 300 mg daily	Well tolerated	Headache	Hepatitis B activity
Emtricitabine (FTC)	200 mg daily	Well tolerated	Rash	Hepatitis B activity
Didanosine (ddI)	250 mg daily if <60 kg OR 400 mg daily if >60 kg	Peripheral neuropathy Gastrointestinal upset	Pancreatitis Lactic acidosis	Overlapping toxicity—so should not be used together
Stavudine (d4T)	30 mg daily if <60 kg OR 40 mg daily if >60 kg	Peripheral neuropathy Lipoatrophy*	Pancreatitis Lactic acidosis	
Abacavir (ABC)	600 mg daily	Well tolerated	Hypersensitivity reaction*	*Almost all patients who develop hypersensitivity are HLA-B57*01 positive—therefore screening recommended prior to commencement
Tenofovir (TDF)	300 mg daily	Well tolerated	Renal impairment and/or Fanconi's syndrome	Hepatitis B activity

\*Lipoatrophy can occur with all the NRTIs but is more commonly seen with stavudine and zidovudine.

when they are used. Interactions occur with all members of the class but to varying degrees; delavirdine is an inhibitor of CYP450 3A4, nevirapine is an inducer of the same enzyme, and efavirenz both inhibits and induces 3A4. As a class the NNRTIs also generally have a low genetic barrier to resistance which can lead to early resistance in the setting of poor adherence.

Another idiosyncrasy to NNRTIs is their extremely long half-life. This needs to be considered when they are used as part of combination therapy—ceasing all three drugs simultaneously will in fact result in NNRTI monotherapy for 1–2 weeks which can inadvertently lead to NNRTI resistance rapidly. Techniques to avoid this include a staggered cessation of ART, i.e., NNRTI first and continue the two (or more) other agents for 5–7 days before ceasing all together; or alternatively switch the NNRTI to a PI and continue this treatment for up to a month before ceasing all together.<sup>68</sup>

Nevirapine may induce a potentially fatal hypersensitivity reaction in individuals, primarily consisting of the development of a rash and hepatitis. This side effect was later found to be fairly predictable by the patient CD4 count at initiation of treatment. Men with a CD4 count greater than 400 cells/ $\mu$ L and women with a CD4 count greater than 250 cells/ $\mu$ L are at significantly higher risk of developing this toxicity.<sup>69</sup> The severity of this hypersensitivity reaction cannot be understated and absolutely contradicts future use of nevirapine.

Efavirenz has now become one of the mainstays of primary ART for a number of reasons. It is fairly well-tolerated—the most common side effect being that of central nervous system toxicity. For the majority of patients this may consist of vivid dreams, some sleep disturbance, dizziness or difficulty in concentrating. In a small percentage of patients, EFV may actually potentiate psychiatric illness and as such it is not recommended in patients with current psychiatric disease or severe past psychiatric illness.

**Table 114.2:** Non-nucleoside Reverse Transcriptase Inhibitors

NRTI	Dosing	Common side effects	Less common side effects	Other features
Nevirapine (NVP)	200 mg daily for 14 days then increase to 200 mg BD	Rash Abnormal LFTs	Steven-Johnson syndrome Hepatitis	Induces its own metabolism—explaining the unusual dosing schedule when initiating
Delavirdine (DLV)	400 mg TDS	Rash Hepatic transaminitis		Gastric acid lowering drugs inhibit DLV absorption
Efavirenz (EFV)	600 mg daily	Rash—can treat through unless worsening or concurrent hepatitis Central nervous system side effects	Severe depression—possibly leading to suicidality	Dyslipidemia Lipodystrophy
Etravirine (ETV)	200 mg BD	Rash—may resolve with continued use	Hypersensitivity reaction Nausea	

Etravirine was licensed in 2008 and became the first “second” generation NNRTI with activity against some, but not all, NNRTI-resistant viruses in patients who have previously failed an older NNRTI regimen.<sup>70</sup> In fact there are a number of mutations in the viral reverse transcriptase associated with ETV resistance and there appears to be a cumulative effect of these mutations on the efficacy of ETV.<sup>71</sup>

The phase 3 DUET studies examined the use of etravirine in treatment-experienced patients with known NNRTI resistance. All patients received a background regimen including boosted darunavir, NRTIs, with or without enfuvirtide. By 96 weeks significantly more patients who received etravirine, compared with placebo, achieved a viral load of less than 50 copies/mL (57% vs. 36%,  $p < 0.0001$ ).<sup>70</sup> Adverse events were similar between groups except for the incidence of rash (21% vs. 12%,  $p < 0.0001$ ).

## PROTEASE INHIBITORS

After integration into the host genome, HIV is transcribed into an RNA polyprotein consisting of Gag and Pol proteins, which requires cleavage by viral protease to make smaller, complete HIV virions. Protease inhibitors (PIs) prevent this cleavage with the consequent production of viral RNA in a non-infectious form.

PIs are all metabolized by the cytochrome P450 3A4 enzyme and this mechanism is exploited therapeutically with the use of ritonavir “boosting”. Ritonavir (RTV) is a PI with anti-HIV activity, but significant side effects are seen—primarily gastrointestinal disturbance and lipid abnormalities at doses required to achieve a therapeutic effect.<sup>72</sup> Ritonavir however also

inhibits the CYP 3A4 enzyme, preventing the clearance of drugs metabolized by this mechanism and hence increasing drug levels and half lives substantially. This boosting phenomenon occurs with quite small doses of RTV and allows for a lower dose of the concomitant PI to be administered—often as a single daily or twice daily dose. Boosting also reduces the risk of development of resistance by ensuring adequate drug levels of the primary PI. In general, most PIs are recommended for use with RTV boosting (often abbreviated as “/r”), especially when used for patients who are antiretroviral experienced and have developed some PI resistance mutations already.<sup>17</sup> Atazanavir (ATV) can be used without RTV but requires a larger dose (400 mg) in this scenario and may not be as effective in combination with some other antiretrovirals, such as with tenofovir-emtricitabine.<sup>73</sup>

As a group the PIs are all associated with dyslipidemia to varying degrees although atazanavir and darunavir tend to be more lipid friendly in comparison with older agents. Other class side effects appear to be an increased risk of hyperglycemia, lipodystrophy (see above), and a possible association with an increased risk of bleeding in hemophiliac patients.<sup>44</sup> Gastrointestinal disturbance is also common with all PIs including nausea, abdominal pain, and diarrhea—these symptoms are all somewhat exacerbated by the concomitant use of ritonavir boosting. Specific side effects are listed in Table 114.3.

## CCR5 CO-RECEPTOR ANTAGONISTS

Binding to CD4 receptors, the HIV virus requires attachment to a co-receptor to infect a host cell. Most commonly, this co-receptor is the CCR5 chemokine receptor, especially in early infection.

**Table 114.3:** Protease Inhibitors

PI	Dosing (PI/ritonavir)	Common side effects	Less common side effects	Other features
Indinavir (IDV)	800 mg/100 mg BD OR 800 mg/200 mg BD OR 400 mg/400 mg BD	Nephrolithiasis Gastrointestinal adverse effects	Nephrolithiasis Nephrotoxicity	
Saquinavir (SQV)	1600 mg/100 mg daily (soft gel cap) OR 400 mg/100 mg BD (hard gel cap)	Gastrointestinal adverse effects Lipodystrophy	Hepatitis	
Atazanavir (ATV)	300 mg/100 mg daily OR 400 mg daily (without RTV)	Hyperbilirubinemia	Nephrolithiasis	Good lipid profile
Lopinavir (LPV)	400 mg/100 mg BD	Gastrointestinal adverse effects esp. diarrhea		Dyslipidemia particularly an issue
Darunavir (DRV)	800 mg/100 mg daily in treatment naïve patients OR 600 mg/100 mg twice daily in treatment experienced patients	Well tolerated	Rash	Good lipid profile
Tipranavir (TPV)	500 mg/200 mg BD	Gastrointestinal adverse effects Hyperlipidemia	Rash Intracranial hemorrhage	
Fosamprenavir (FPV)	1400 mg/200 mg daily OR 700 mg/ 100 mg BD in treatment naïve patients OR 700 mg/100 mg BD in treatment experienced patients	Gastrointestinal upset Rash	Nephrolithiasis	

Alternatively, and more commonly with patients infected for a number of years, HIV may use the CXCR4 receptor or both CCR5 and CXCR4, known as dual-tropic virus. However, primary infection with X4 virus alone remains uncommon.<sup>74</sup>

Maraviroc (MVC) is currently the only marketed CCR5 antagonist. The initial studies of MVC in treatment-experienced patients, MOTIVATE 1 and 2, randomized a total of 1049 patients to one of the three arms, once or twice daily maraviroc and placebo, with an optimized background treatment (OBT) regimen<sup>75</sup>—generally defined in HIV trials as the combination of antiretrovirals, dictated by resistance testing, that is likely to retain the most activity against each individual's virus. Approximately 44% of patients screened for the study still had R5 tropic virus despite triple antiretroviral class treatment experience. At week 48, patients receiving maraviroc had a greater mean reduction in HIV viral load and more often had a viral load of less than 50 copies/mL (once daily maraviroc 42% and twice daily maraviroc 47% compared with placebo 16% in MOTIVATE 1; 45% in both maraviroc arms compared with 18% placebo in MOTIVATE 2. Maraviroc was also associated with a greater CD4 cell increase. These benefits have been shown to be durable out to 96 weeks.<sup>76</sup> It is possible that even more patients could achieve virological suppression with the concomitant use of newer antiretrovirals, such as darunavir, etravirine, and raltegravir that were not allowed within the MOTIVATE studies' protocol.<sup>75</sup>

The MERIT study subsequently followed and compared maraviroc twice daily against efavirenz both with an NRTI backbone of lamivudine-zidovudine.<sup>77</sup> All patients entering the study had R5 tropic virus as determined by original Trofile assay. The initial intention to treat (ITT) analysis compared a total of 721 patients and although a larger CD4 cell count increase was seen in the maraviroc arm, by week 48 the proportion of patients who achieved a viral load of less than 50 copies/mL was 65.3% with maraviroc compared with 69.3% with efavirenz. This result failed to reach predetermined non-inferiority criteria and the discrepancy was even higher in patients with viral loads greater than 100,000 copies/mL (59.6% vs. 66.6%). A newer Trofile assay, much more sensitive to lower proportions of X4 virus was subsequently developed and samples from the MERIT study were reanalyzed—14.7% of the original study population were found to have dual tropic virus. Using an ITT analysis with patients with R5 virus only, as per the new assay, demonstrated that maraviroc was indeed non-inferior to efavirenz in virological suppression at week 48 (68.5% vs. 68.3%).<sup>74</sup>

After initial concern over cardiac QT interval prolongation, MVC was shown to be safe at current therapeutic doses and is generally well-tolerated. Dosing can be confusing due to a number of drug interactions, and therefore the dose of MVC may need to be increased or decreased according to concomitant medications.

## FUSION INHIBITORS

The sole agent within this class is enfuvirtide (T20). T20 acts by inhibiting the HIV gp41 protein that prevents an HIV virion

from fusing with a host cell membrane. This unique mechanism of action allows T20 to have efficacy even in patients heavily experienced with other classes of ART, in the context of a combination antiretroviral therapy.

The TORO study<sup>78</sup> was performed in treatment-experienced patients who were randomized to OBT with and without the addition of T20. At 48 weeks, 30.4% of patients receiving T20 were virally suppressed below 400 copies/mL and 18.3% below 50 copies/mL, as compared with 12.0% and 7.8% who received OBT alone. A large number of patients on OBT failed therapy were switched to the T20 arm during the study. By 96 weeks, of those patients receiving T20 who completed the study, 26.5% had a viral load of less than 400 copies/mL and 17.5% were having less than 50 copies/mL.<sup>79</sup> Patients who retained activity to lopinavir/ritonavir, a new boosted PI at the time of the study, had improved efficacy compared with those who had previously been treated with it.<sup>78</sup> This would suggest that in patients with significant treatment experience but who still retained some activity from newer PIs (e.g., darunavir and lopinavir) would achieve better efficacy than the numbers stated above—especially if combined with newer antiretrovirals, such as raltegravir, etravirine, and maraviroc.

The main shortfall of T20 is its mode of administration. Subcutaneous injections, twice daily, which result in injection site reactions in the majority (>95%) of patients are a significant deterrent to its uptake and result in discontinuation in 7–10% of patients in the short term,<sup>79</sup> but it is otherwise well-tolerated.<sup>80</sup>

## INTEGRASE STRAND INHIBITORS (INSTI)

Integrase inhibitors are the latest class of ART developed and have revolutionized salvage therapy as well as providing a new option in the treatment of treatment naive patients. Integrase is a viral enzyme that allows HIV DNA, formed by reverse transcription, to be inserted into the host genome. Integrase inhibitors inhibit the viral integrase enzyme, prohibiting viral integration and as this enzyme is a novel target in antiretroviral therapy, integrase inhibitors will generally have activity against viruses that have failed other classes of ARVs in the past.<sup>81</sup> Raltegravir is the first marketed INSTI but a number of others are likely to follow in coming years.

BENCHMRK 1 and 2 were randomized, placebo-controlled trials involving 699 patients with triple-class antiretroviral resistance who received OBT with raltegravir or placebo. At week 48, 62.1% of patients receiving raltegravir achieved a viral load of less than 50 copies/mL, as compared with the placebo group where only 32.9% of patients reached this milestone ( $p < 0.001$ ).<sup>81</sup> This benefit was durable out to 96 weeks.<sup>82</sup>

Following on from this, the STARTMRK study was conducted—a randomized double-blind trial in antiretroviral naive patients comparing raltegravir against efavirenz, with a nucleoside backbone of tenofovir-emtricitabine. At 96 weeks, raltegravir was found to be non-inferior to efavirenz in regard to virological suppression (81% patients on raltegravir and 79%

on efavirenz achieved a viral load of less than 50 copies/mL;  $p < 0.001$ ).<sup>83</sup> The raltegravir arm had a faster rate of virological suppression and was associated with a greater CD4 count increase compared with the efavirenz arm at 48 weeks of treatment,<sup>84</sup> but there was no significant difference between arms at 96 weeks.<sup>83</sup> Despite this faster rate of virological suppression, the incidence of immune reconstitution syndrome was similar in both groups. The clinical benefit or harm of achieving immune restoration sooner has not been demonstrated yet.

The main clinical benefit of raltegravir lies in its tolerability. Patients randomized to raltegravir in STARTMRK experienced significantly less adverse effects compared to efavirenz (47% vs. 78%;  $p < 0.001$ ), although discontinuation rates were not dissimilar (4% vs. 6%;  $p = 0.333$ ).<sup>83</sup> One concern raised in the studies listed above was the rate of newly diagnosed, recurrent or progressive malignancies—3.5% of raltegravir-treated patients in BENCHMRK, compared with 1.7% of those receiving placebo—this equated to a relative risk of cancer of 1.54 (95% CI, 0.50–6.34)<sup>81</sup>—the implications of which remain unknown as carcinogenicity was not seen in preclinical studies. Drug interactions may also occur, but unlike many other antiretrovirals that are metabolized by the cytochrome P450 system, raltegravir is affected by changes in the enzyme uridine diphosphate glucuronosyltransferase 1A1.<sup>85</sup>

## What to Start?

After the decision is made to commence treatment, the selection of the first ART regimen is important given the clear evidence for lifelong therapy.<sup>4</sup> With this in mind several factors play a role in deciding the choice of agents used. First and foremost is obviously virological efficacy and robustness, but other considerations include pill burden, toxicity, co-morbidities and drug interactions, and finally patient preference.<sup>44,67</sup>

Most recommendations suggest the use of two NRTIs in combination with a third agent from a different class with current evidence suggesting the use of an NNRTI, PI or INSTI.<sup>44,67</sup> In the past there was some consideration given to triple or even quadruple NRTI regimens but these have been clearly shown to be inferior in virological response<sup>86–88</sup> and with the advent of some newer classes of ART, such as the integrase inhibitors or CCR5 co-receptor antagonists, the need to reserve drugs in case of future resistance is less of an issue.

The preferred NRTI backbone currently is tenofovir–emtricitabine (TDF–FTC) primarily due to its once daily dosing and low side effect profile. In studies comparing its efficacy against zidovudine–lamivudine (AZT–3TC), TDF–FTC was superior in terms of virological suppression at 144 weeks (71% vs. 58%;  $p = 0.004$ ), less discontinuation due to side effects (5% vs. 11%;  $p = 0.01$ ), less lipodystrophy ( $p < 0.001$ ) and fewer patients developed the M184V mutation ( $p = 0.02$ ).<sup>89</sup>

Up until recently the fixed-dose combination (FDC) of abacavir and lamivudine was one of the preferred components of the initial ART regimen. It is now recommended as an alternative,

rather than a first-line option for a number of reasons. ACTG A5202 demonstrated more virological failures in antiretroviral naive patients treated with abacavir–lamivudine as compared to those treated with tenofovir–emtricitabine in those with high viral loads ( $>100,000$  copies/mL)<sup>90</sup> although this effect was not confirmed in the subsequent HEAT trial.<sup>91</sup> Also more recently, the observation of greater cardiovascular risk in patients currently on abacavir or having received it within the past 6 months<sup>92</sup> has resulted in a reduction in its use—although the biological mechanism for the increased cardiovascular risk is yet to be determined.<sup>93</sup> In its favor is its high central nervous system (CNS) penetrance,<sup>94,95</sup> which may be of benefit in those with neurocognitive diseases and it also has once daily dosing. No patient should start ABC or a combination containing ABC until they are confirmed to be HLA-B5701 negative to avoid potentially fatal hypersensitivity reactions.<sup>66</sup>

The FDC of zidovudine–lamivudine (AZT–3TC) is also an option for the NRTI backbone but is generally not considered a preferred first-line combination. AZT–3TC requires twice a day dosing and has more side effects experienced in general when compared with TDF–FTC<sup>89</sup> or ABC–3TC<sup>96</sup>. However, there is considerable clinical experience with its use and the safety profile is well-known. It remains a preferred agent in the setting of pregnancy.

In combination with an NRTI backbone, there are several options for the third first-line agent used. Current evidence supports the use of either an NNRTI, PI, or INI.

Efavirenz remains the preferred NNRTI of choice. In naive studies efavirenz has been demonstrated to achieve sustained virologic suppression for more than 5 years. In comparison with PIs, efavirenz has been shown to be superior to indinavir and lopinavir–ritonavir, and also comparable to atazanavir.<sup>44,97,98</sup> Of concern is the low genetic barrier to resistance within the NNRTI class in general. For this reason, baseline genotypic analysis is important to exclude pre-existing transmitted NNRTI resistance which is estimated to occur in between 2.3% and 9.1% of ART naive patients.<sup>99–101</sup> The CD4 cell count constraints on the use of nevirapine (see above)<sup>69</sup> limits its use in the ART naive setting except for late presenting patients with low CD4 cell counts. The introduction of the FDC of tenofovir, emtricitabine, and efavirenz further reduces pill burden to a single pill, once daily which potentially assists with compliance of treatment that will need to be lifelong.

Within the PI class, atazanavir and darunavir are the preferred agents for first-line use. Atazanavir is a once daily PI that was first shown to be non-inferior to efavirenz in treatment of ART naive patients in combination with a zidovudine–lamivudine NRTI backbone.<sup>97</sup> By week 48, 70% of patients treated with atazanavir had a viral load of less than 400 copies/mL, as compared with 64% of patients receiving efavirenz. Increases in CD4 counts were similar between the treatment arms and atazanavir was well-tolerated in terms of lipid profile. Hyperbilirubinemia only rarely led to drug discontinuation ( $<1\%$ ).

The CASTLE study was a randomized, open label study comparing ritonavir-boosted lopinavir twice daily with boosted atazanavir once daily.<sup>102</sup> In total 883 patients were enrolled over

96 weeks. By the end of the study, the atazanavir arm achieved non-inferiority in virological suppression (74% vs. 68%;  $p < 0.05$ ). More patients complained of gastrointestinal side effects in the lopinavir arm, although conversely there were more instances of hyperbilirubinemia in the atazanavir arm. Rates of suppression were similar regardless of HIV RNA cut-off or baseline CD4 count.

In the ARTEMIS trial, 689 ART naive patients were randomized to ritonavir-boosted darunavir (800 mg) or ritonavir-boosted lopinavir. At 48 weeks, darunavir was shown to be non-inferior to lopinavir with regards to virological suppression (84% vs. 78%;  $p < 0.001$ ).<sup>103</sup> By 96 weeks of follow-up darunavir was superior in virological suppression after intent-to-treat analysis (79% vs. 71%;  $p = 0.012$ ) and this difference was mainly seen in those with a CD4 count less than 200 at baseline (79% vs. 65%;  $p = 0.009$ ) and those with a high baseline viral load ( $\geq 100,000$  copies/mL) (76% vs. 63%;  $p = 0.023$ ).<sup>104</sup> Sub-optimal adherence to darunavir, compared with lopinavir, had less of an effect on rates of virological suppression (76% vs. 53%;  $p < 0.01$ ).<sup>105</sup>

When choosing between PIs and NNRTIs, there may be several factors to consider. Efficacy is generally not a major discriminating factor but rather tolerability. The single pill formulation of TDF-FTC-EFV is a significant incentive for patients concerned about pill burden or with compliance issues. This regimen is generally well-tolerated although a small percentage will develop rash, necessitating discontinuation, and the CNS side effects of efavirenz can be disconcerting for some patients, or dissuade against use in others with pre-existing psychiatric disease. PI-based regimens are less lipid friendly and are generally associated with more GIT disturbance due to the concomitant use of ritonavir.<sup>44</sup>

More recently, the integrase inhibitor, raltegravir (RAL) was shown in the STARTMRK trial to be non-inferior with regard to viral suppression to efavirenz (81% vs. 79%;  $p < 0.001$ ) when used in combination with TDF-FTC,<sup>83</sup> although no comparison has been made yet with PI-based regimens. In comparison to efavirenz, patients treated with raltegravir experienced fewer side effects in general (47% vs. 78%;  $p < 0.001$ ) although serious adverse events and toxicity requiring discontinuation of treatment was similar between groups. Raltegravir also had a better lipid profile compared with efavirenz. This data prompted its inclusion as a preferred first-line agent although some have concerns about its use as a first-line agent when it has significant benefits currently for the treatment of multi-class experienced patients.<sup>82,106</sup> Similar to NNRTIs, it too has a low genetic barrier to resistance.<sup>107</sup>

The above regimens are only recommendations and as mentioned already, there are numerous factors to consider when initiating patients on ART for the first time. With the number of agents available a large number of combinations are possible—there are a few combinations that are not recommended and these are listed in the DHHS guidelines.<sup>44</sup>

## SECOND-LINE OPTIONS

A change in ART regimen may be required either for viral resistance, drug intolerance, toxicity or due to potential drug interactions with concomitant medications.

Virological failure is defined as failure to fully suppress viremia ( $<50$  copies/mL at 24 weeks) or recrudescence after previous suppression, and it always warrants a change in ART regimen. Virological failure, even if at low levels of viremia, is associated with the development of resistance mutations<sup>108–111</sup> that will limit future therapeutic options as they accumulate. However, very low-level viremia ( $<1000$  copies/mL) may not necessarily warrant a change in ART regimen immediately, but rather careful observation.<sup>44</sup> Detectable viremia should be confirmed by a second test prior to considering a change in therapy. ART failure may sometimes be due to previously archived resistance not seen on the baseline genotype; transmitted resistance is becoming an increasing problem with the increasing availability of ART, rates of 9.1% were reported in a recent European surveillance report.<sup>99</sup> More commonly, viral resistance develops on ART due to inadequate compliance or drug interactions. It is important to address these issues prior to changing therapy.

Drug toxicity or poor tolerance is often easier to manage because with the number of ARVs available today, patients can often be switched to another drug within the class without the need for new resistance testing and with good effect. Substituting a single drug to one from a different class to manage drug toxicity may be reasonable in the setting of a fully suppressed viral load. However, it is important to have confidence that the remaining two (or more) antiretrovirals will have enough activity to maintain a barrier to development of resistance and to consider any potential drug interactions that would compromise efficacy.<sup>112</sup> Similarly, drug interactions are less of an issue today due to the number of antiretroviral options available for use.

Despite more than 25 years of clinical antiretroviral drug trials, there is very little evidence for second-line treatment following on from first regimen failure.<sup>113</sup> An important principle to adhere to is to never change a single drug in a virologically failing regimen—a minimum of two new fully active, and ideally three, antiretroviral drugs should always be introduced regardless of the HIV genotype which may not detect all mutations present. Results from the HIV genotype analysis, taken while the patient is taking the failing regimen (or within 4 weeks of ceasing it) guide the selection of the new antiretroviral regimen.<sup>112</sup>

Patients who fail on an NNRTI-containing regimen will often develop resistance to all the “first generation” NNRTIs and hence lose activity to the entire class except perhaps for etravirine, whose activity varies according to which NNRTI mutations have developed.<sup>114,115</sup> NRTI mutations frequently develop following NNRTI resistance to essentially lead to single ARV class therapy in this setting.<sup>112</sup> The DUET 1 and 2 studies showed that etravirine still has considerable efficacy (see above) in patients with known NNRTI and PI resistance, although all patients did receive ritonavir-boosted darunavir as well.<sup>70</sup>

On the other hand, failure on a protease inhibitor containing regimen does not necessarily infer the development of broad resistance mutations for PIs due to their inherent higher genetic barrier to resistance.<sup>99,116,117</sup> In fact, major PI resistance mutations

occur in less than 1% of patients failing their regimen for the first time.<sup>112</sup> If major PI mutations do occur, then a second generation drug such as ritonavir-boosted darunavir or tipranavir will likely still have efficacy as demonstrated by the RESIST and POWER studies.<sup>118–120</sup> One of the few trials to assess choice of ART at first virological failure was the TITAN study,<sup>121</sup> which compared the use of boosted lopinavir to boosted darunavir containing regimens in patients with virological failure. It showed that at 48 weeks, darunavir was superior to lopinavir in terms of viral suppression below 400 copies/ $\mu$ L but especially so in patients who had previously been treated with a PI-containing regimen.

A number of the more recently developed antiretrovirals have demonstrated benefits in the setting of heavily treatment-experienced patients. As mentioned earlier, maraviroc in MOTIVATE, raltegravir in BENCHMRK, enfuvirtide in TORO, etravirine in DUET, and darunavir in the POWER studies have all demonstrated clinical efficacy in the setting of multiple ARV class resistance. The final guide in choosing active drugs for a salvage regimen is the use of combined results of genotypes from throughout a patient's treatment history. However the combination of ritonavir-boosted darunavir, etravirine, and raltegravir has shown promise in the treatment of multi-drug-resistant HIV.<sup>106</sup>

Finally, it is possible to have discrepant HIV control within an individual patient, i.e., in different body compartments—the most obvious being the central nervous system (CNS). Owing to the variable penetration of ARVs into the CNS,<sup>94,95</sup> patients may have virological suppression in plasma but have replicating virus within the CNS. While this remains an uncommon occurrence, it may be important to consider the possibility in patients on cART who present with HIV-associated neurological and psychiatric disorders.<sup>122</sup>

## Treatment in Special Groups

### PREGNANCY

Pregnancy in HIV-positive women poses a number of unique considerations: firstly the effect of pregnancy on HIV progression in the mother; secondly the risk of HIV transmission to the child; thirdly the change in drug metabolism and pharmacokinetics in different stages of pregnancy, and lastly the risk of ART on the developing fetus.

Pregnancy appears not to have any major deleterious effects on HIV in the mother. Despite some initial concerns that HIV progressed more rapidly during pregnancy, there is no increase in mortality compared with uninfected mothers, no change in HIV viral load, and no increased risk of opportunistic infections or AIDS events.<sup>123</sup> CD4 cell counts do drop during pregnancy but CD4 percentages remain the same<sup>124</sup> reflecting a physiological change in lymphocyte numbers rather than a true fall in immunity.

### Antepartum Antiretroviral Therapy

Of more concern to mothers is the risk of vertical transmission to their child. In the absence of ART, mother to child transmission

(MTCT) occurs in approximately 25% of deliveries.<sup>125</sup> The majority of transmission occurs during labor and delivery, but approximately a third of transmission will occur during pregnancy, especially in the later stages of gestation. ART has been clearly documented to reduce the risk of MTCT. The first study of ART in pregnancy with zidovudine monotherapy (PACTG 076)<sup>125</sup> demonstrated a 68% reduction in transmission rate and although benefit of the same magnitude with single agent therapy has not been reproduced, a number of observational studies confirmed the benefit of monotherapy.<sup>9,126,127</sup> There have been no randomized studies of cART against placebo for obvious reasons but again observational studies suggest that transmission rates of less than 2% can be achieved.<sup>128,129</sup>

The maternal viral load at the time of delivery is a key determinant of transmission risk<sup>130</sup> and hence virological suppression during pregnancy managed with cART is now considered standard of care<sup>131</sup> in many countries. There are some who would still suggest that in women with low viral loads, zidovudine monotherapy may be sufficient, especially when combined with elective caesarean section.<sup>132,133</sup>

In favor of monotherapy, ART has been associated with an increased rate of preterm delivery<sup>134,135</sup> independent of maternal age. The European collaborative study found that the risk of prematurity was greater with cART than with monotherapy (OR 1.43; 95% CI 1.1–1.86;  $p=0.01$ )<sup>133,134</sup> and hence the additional benefit of cART over monotherapy in terms of MTCT should be weighed against the increased risk of preterm delivery.<sup>136</sup> Townsend et al. estimated that to prevent 100 vertical transmissions by using cART, as opposed to monotherapy, 63 additional preterm deliveries would result (95% CI 6–196) of which, 23 would occur before 32 weeks gestation. Other studies have not associated ART with increased rates of premature births and a meta-analysis suggested that overall there was no strong association although many different populations were studied, each with their own set of confounders.<sup>137</sup> When choosing between monotherapy and cART, it is important to decide on the primary aim of therapy—prevention of transmission to the infant where monotherapy may be enough in some circumstances, or control of maternal HIV disease with combination treatment, which is generally considered the standard of care.<sup>44,67</sup>

Different antiretroviral drugs vary in their safety record in pregnancy. Agents with the most safety data include zidovudine–lamivudine (AZT–3TC) fixed-dose combination (FDC) (Combivir), together with lopinavir–ritonavir (Kaletra) or nevirapine in those women with low CD4 cell counts.<sup>131</sup> Zidovudine (AZT) is generally recommended as part of cART in pregnant women as it has the greatest evidence and safety data to support it. This is not to say that non-AZT containing regimens cannot be used if there are reasons why AZT should not be used; for example, if compliance, side effects or resistance are an issue; or if the woman in question is already on a fully suppressive non-AZT containing regimen.<sup>131</sup>

There have been previous concerns regarding the use of efavirenz, primarily related to congenital central nervous system

abnormalities including neural tube defects (NTDs) that were seen in pre-clinical testing in primates. Given these concerns, efavirenz has been given a category D safety in pregnancy rating and recommendations are generally that pregnant women should be switched off it as soon as possible and perhaps not even commenced in women of child-bearing potential. Case reports and retrospective case series of birth defects have been published, as well as a recent meta-analysis which all suggest that there is no significant difference in the rate of congenital abnormalities seen in children born to mothers treated with efavirenz.<sup>138</sup> Obviously this data must be interpreted with a degree of caution as it is not truly randomized, prospective evidence, however, the initial concern regarding efavirenz may not be as great as once thought. The alternative NNRTI, nevirapine, has a good safety record if initiated in women with a CD4 count below 250 cells/ $\mu$ L, thereby avoiding the increased risk of hypersensitivity, rash, and hepatic toxicity associated with use at higher levels of immunity.<sup>69</sup>

Other reverse transcriptase inhibitors of concern in pregnancy include tenofovir, which despite its strong preference in first-line treatment of HIV, is used with caution antenatally due to animal reports of fetal osteopenia and bone demineralization in children.<sup>131</sup> Protease inhibitors (PIs) are generally well-tolerated with the most safety data belonging to the FDC of lopinavir-ritonavir. Atazanavir and indinavir pose theoretical concerns of neonatal jaundice and kernicterus, although this has not been borne out in clinical studies.<sup>131</sup> Drug levels of PIs may be reduced in pregnancy and as such ritonavir boosting is generally recommended.

Other than the teratogenic potential of ART it is also important to remember the major physiological changes in pregnancy that affect pharmacokinetics and pharmacodynamics of these medications which may alter dosing recommendations.

### Antiretroviral Therapy during Labor

In addition to antepartum AZT monotherapy, the PACTG 076 study also treated women with intravenous AZT during labor.<sup>125</sup> An infusion commenced 3 hours prior to elective caesarean section, and continued for an hour post delivery has become standard practice, regardless of whether the mother received cART during her pregnancy or not.<sup>131</sup> AZT confers benefit to both the mother and the newborn as it crosses the placenta, and is likely to still be useful in the setting of apparent AZT resistance in the mother.<sup>139</sup>

### Caesarean Section

Elective caesarean section is another method utilized to reduce the risk of vertical transmission. During vaginal delivery a newly born infant is exposed to maternal blood and fluids in the birth canal and hence delivery by caesarean section, if performed prior to the rupture of membranes, eliminates this risk. Adjusting for AZT monotherapy, caesarean section was shown to reduce the risk of vertical transmission by 57% (OR 0.43, 95% CI 0.33–0.56).<sup>140</sup> Together with AZT treatment, the risk of transmission following

delivery is reduced significantly (OR 0.07, 95% CI 0.09–0.19). This magnitude of benefit becomes less clear once cART is used given the greater viral suppression that is achieved. In one prospective study of caesarean section, no significant benefit on vertical transmission was seen once cART was accounted for (OR 0.52, 95% CI 0.14–2.03;  $p = 0.36$ ) (MTCT in HIV, CID 2005). Hence, the reduction in risk of transmission of HIV but the increased risk associated with caesarean section may not be acceptable to a patient virologically suppressed on cART and these risks need to be discussed with women during their antenatal care.<sup>131</sup>

### Post-Partum Antiretroviral Therapy

Following delivery, the decision to continue ART should be made after consultation with the mother and taking into account her immune status and co-morbidities. It may be that she would fulfil general criteria requiring treatment in non-pregnant adults and as such it would be advisable to continue ART. If not, it is not unreasonable to cease ART. Mothers treated with an NNRTI as part of their cART antenatally need to be aware of the prolonged half lives of NNRTIs that may require either a staggered discontinuation (i.e., NNRTI first, then NRTIs a minimum of 1 week later) or perhaps substitution of the NNRTI with a PI for a month before ceasing all drugs. These steps reduce the risk of developing NNRTI resistance upon cessation of ART.<sup>131</sup>

### Breast Feeding

Breast feeding for infants in industrialized and middle-income countries is not recommended due to the clearly documented risk of HIV transmission via breast milk.<sup>141</sup> This can occur despite adequate maternal ART as concentrations of ART within breast milk can be erratic—either high leading to potential infant toxicity; or low—promoting development of viral resistance. This recommendation differs from the recommendations on breast feeding in resource limited settings where the positive benefits of breast feeding on childhood morbidity and mortality far outweigh the risks of HIV transmission.<sup>142</sup>

### Newborn Care

Given maternal antibodies can persist in the newborn for 12–18 months, HIV infection of the infant is made by the presence of HIV DNA in blood on two different occasions, 1 month after delivery. Until infection is confirmed or excluded, the newborn should receive prophylaxis with zidovudine (2 mg/kg, four times daily if born at term) for 6 weeks.<sup>125,131</sup>

### Co-Infection With HEPATITIS B/C

HIV has been clearly demonstrated to result in a faster clinical course of viral related liver disease in both hepatitis B (HBV) and hepatitis C (HCV)<sup>143,144</sup> and consequently, treatment of HIV in patients with co-infection should be of benefit.

A number of the anti-HIV medications are active against HBV as well (and are available as monotherapy for treatment of HBV monoinfection), e.g., lamivudine, emtricitabine, and tenofovir. To avoid the development of HIV resistance to single antiretroviral use, the decision to treat HBV often necessitates initiation of treatment of HIV with cART—most often using the FDC of tenofovir and emtricitabine, Truvada, together with a third agent from a different class. Caution must be taken in ceasing ART in a patient with chronic HBV as the consequent reduction in immunity and flare in HBV replication can lead to a clinical flare of hepatitis.<sup>145</sup>

For dual infection with HIV and HCV there is no issue with overlapping activity of antiviral medications used and hence it is possible to treat either disease independent of each other. However, by improving the immune response with cART, improved responses in HCV treatment with pegylated interferon and ribavirin are seen.<sup>146</sup> Given the significant commitment involved for patients to undergo a 6 or 12 month course of HCV therapy with its associated side effect profile, it would seem prudent to treat the HIV first, if possible, to ensure the best chance of a sustained virological response (SVR), especially in the cases of genotypes 1 and 4 infection. For patients with higher CD4 cell counts not necessitating ART on their own merit, treatment of HCV infection first may avoid potential overlapping drug toxicity and interactions.<sup>67</sup>

Obviously, there is some concern of increased rates of liver toxicity with cART in patients with pre-existing liver disease, but generally this is not clinically relevant except for the case of potentially fatal nevirapine hypersensitivity reaction when patients are started at high CD4 cell counts.<sup>69</sup> In fact treating the underlying liver disease, e.g., clearing HCV infection can reduce the rates of hepatotoxicity seen with ART.<sup>147</sup>

## PRIMARY HIV INFECTION

In general, treatment of primary infection is not recommended especially if the patient is asymptomatic.<sup>67</sup> When symptomatic, the acute seroconversion illness is generally self-limiting and so the benefit of early ART remains largely theoretical—preservation of immune function, reduction in disease progression, reduction in viral reservoirs and decrease in the risk of HIV transmission.<sup>44,148</sup> However, this approach would essentially commit the individual to lifelong therapy. Given the potential risks and benefits of this approach remain unproven, treatment of primary infection is generally not recommended.

## ADOLESCENTS

Adolescents are often grouped with adults in reports and studies in HIV, but adolescents infected with HIV pose a unique set of issues and care needs due to a variety of clinical, behavioral, developmental, and psychosocial changes that occur at this developmental stage. Concerns over disclosure, adherence, and sexual identity are just some of the issues that face children entering adulthood that is complicated by the natural shift in

responsibility to themselves for the management of a chronic, and currently incurable, disease.

Adolescents with HIV can be divided into two broad groups—those with perinatally acquired infection and those who have acquired infection through high-risk behavior, either sexually or via injecting drug use.<sup>149</sup>

Those with perinatally acquired infection are likely to have already been exposed to medical care for most of their life, already be on ART, and frequently have drug resistance<sup>150</sup>—all before beginning normal adolescent risk taking behavior and psychosocial development. These adolescents may already have complications because of their HIV status, such as delayed puberty, or from their ART, such as lipodystrophy. Behaviorally acquired HIV-infected adolescents on the other hand are likely to have only been infected recently and may still be coping with the diagnosis—depression and low self-esteem are common. ART initiation may not be an immediate concern but rather disclosure to family and friends, as well as the acceptance of a chronic illness and the incumbent responsibilities that will place on themselves in terms of medical care and ART.<sup>149</sup>

The transition from childhood to adulthood is also accompanied by physiological changes that affect the dosing of ART but very little data exists on the pharmacokinetics and pharmacodynamics of antiretrovirals in adolescence.<sup>151</sup> Some groups advocate dosing adolescents over the age of 12 years old as adults.<sup>152</sup> The US guidelines suggest ART should be dosed according to the Tanner staging of puberty—stage 1 and 2 dosed as children and stage 3 and 4 as adults.<sup>44</sup> There is actually very little clinical data supporting this recommendation but certainly there is evidence of changes in cytochrome P450 metabolism during puberty which could justify using Tanner stage rather than simply being guided by weight or age. Even within these pubertal stages, the growth spurts of adolescence can make dosing unpredictable and patients need to be closely monitored for both effectiveness of ART as well as excess toxicity.<sup>149</sup> Within this context, therapeutic drug monitoring may also assist in selecting the correct doses for individuals.<sup>151</sup>

ART adherence, which is obviously paramount in achieving virological suppression, is often difficult among adolescents—one review of adherence interventional studies in adolescence found a baseline range of between 28.3% and 69.8% compliance.<sup>153</sup> Adherence is difficult to achieve in adolescents in general but within HIV-infected individuals, factors associated with non-compliance include fear of discrimination or accidental disclosure to family and friends, poorer education level and socioeconomic status, substance use, depression, and use of “escape” coping.<sup>153</sup> Mechanisms to improve compliance include parental involvement, informative discussion of side effects, support groups or even short-term hospitalization.<sup>149</sup>

## PEDIATRICS

Children infected with HIV face a more rapid progression of disease compared with infection acquired in adulthood.

**Table 114.4:** Indications for Treatment of HIV-Positive Children

Age	CD4/viral load threshold	Clinical
<12 months	Treat all children <12 months age	
1–5 years old	CD4 < 25% at any viral load	Treat if symptomatic
	CD4 ≥ 25% if viral load > 100,000 copies/mL	
≥ 5 years old	CD4 < 350 cells/mm <sup>3</sup> at any viral load	Treat if symptomatic
	CD4 ≥ 350 cells/mm <sup>3</sup> if viral load >100,000 copies/mL	

Adapted from the Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection, 2010.<sup>155</sup>

Approximately, one quarter of babies with perinatally acquired infection progress to AIDS within a year, the remainder generally progress within 5 years.<sup>154</sup>

Most antiretroviral drugs available for use in adults can be used for the treatment of children<sup>44</sup> although there is obviously less safety data for this group. The main difference for children is the timing of treatment. All babies less than a year old with perinatally acquired infection should receive treatment owing to the rapid progression of untreated HIV in this population. After this first year of life, treatment is guided by CD4 cell counts at different ages (see Table 114.4). All children with CD4 cell counts within the moderate to severe immunosuppression range should receive treatment, as well those who are symptomatic regardless of CD4 cell count.<sup>155</sup>

## Monitoring

Once ART has been commenced in a patient there are a number of issues that need to be monitored by the treating clinician.

## Toxicity

In the short term, it is important to address any immediate toxicity caused by the new regimen. Minimizing and appropriate management of toxicities are important to patient's quality of life and clearly affect medication adherence.<sup>156</sup> Some adverse effects may just be transient and will resolve spontaneously with persistence with medication—this often includes some early gastrointestinal disturbance with the PIs and some scleral icterus with atazanavir. Many patients will continue their ART if reassured that most often these symptoms will improve. On the other hand, severe toxicity needs to be addressed promptly to avoid non-compliance and a loss of trust in the treating clinician.

## Adherence and ART Efficacy

After 1 month of ART it is routine to measure the patient's CD4 cell count and HIV viral load. At least one log fall in viral

load should be expected in patients compliant with their ART regimen effective against a susceptible virus.<sup>44</sup> If the viral load has not fallen by at least this amount it may signify either previously undetected resistance, or more often poor adherence. At least 95% adherence with all doses of medications had been shown to be necessary to achieve virological suppression in patients on cART during the era of unboosted protease inhibitors,<sup>157</sup> but the advent of ritonavir boosting as well as antiretrovirals with long half lives (e.g., efavirenz) has made this requirement more forgiving. The average adherence to boosted PIs appears to be related to efficacy, whereas consecutive missed doses of NNRTIs appear to promote resistance.<sup>158,159</sup> Regardless of the ART regimen, clarifying adherence is important—either by self reporting, pill counting, and therapeutic drug level monitoring for some agents. If adherence appears to be adequate, viral resistance testing is warranted in case the first ART regimen used has unmasked previously undetected viral resistance.

In the longer term, CD4 cell counts and HIV viral loads are generally monitored every 3–4 months—used as a measure of the host immune system. The goal of ART, as mentioned previously, is virological suppression below the level of detection by current assays.<sup>44</sup> Ideally the CD4 cell count should increase significantly also but there are a number of factors involved in its recovery that are independent of the efficacy of ART including nadir CD4 cell count, previous therapeutic failure, HCV co-infection, age, and adherence.<sup>160–163</sup> Viral resistance testing should be performed while the patient is still on ART or at most ceased less than 2–4 weeks prior, if there is consistent evidence of virological failure during ART.<sup>44</sup>

## Immune Reconstitution

Individuals may in fact develop immune responses to organisms previously unrecognized by the host immune system owing to the degree of immunosuppression they experienced prior to commencing ART. The rapid fall in HIV viral load and corresponding increase in CD4 cell count which the patients experience with the initiation of ART has been shown to correlate with the risk of this immune reconstitution inflammatory syndrome (IRIS). Other identified risk factors include a low baseline CD4 count, previously ART naive patients, and those initiated on ART near to the time of diagnosis of an opportunistic infection.<sup>50</sup> Retrospective studies previously suggested quite high rates of IRIS in up to a third of patients commencing ART,<sup>50,164,165</sup> but one prospective study described IRIS occurring in 10.4% of patients.<sup>166</sup>

## Non-AIDS Events

With the advances in ART achieved in the past 20 years, the incidence of opportunistic disease and AIDS related events has fallen dramatically. While the overall mortality rate has fallen, residual viral replication below the limits of detection, with subsequent chronic immune activation and inflammation has led to an increased risk of “non-AIDS” events. HIV-positive patients

experience an increased rate of cardiovascular, renal, hepatic, neurological and bone disease; as well as a higher incidence of non-AIDS-related malignancies.<sup>167–170</sup>

### Summary

In absence of cure, the aim of HIV treatment is the suppression of viremia, which has been shown to lead to immune recovery, increased CD4 cell count, reduced mortality, and reductions in both AIDS related and “non-AIDS” related events.

Combination HIV treatment should certainly commence below a CD4 count of 350 cells/mm<sup>3</sup> with good randomized controlled data to support this. Between 350 and 500 cells/mm<sup>3</sup>, treatment should be considered on an individual patient basis, especially in the setting of hepatitis co-infection, high cardiovascular risk, malignancy, high viral load, rapid CD4 cell count decline, or pregnancy. Above a CD4 cell count of 500 cells/mm<sup>3</sup> some experts would consider combination antiretroviral therapy (cART) on the basis of observational data and hypothesized benefits, but there is little clinical data to support this recommendation currently.

In the setting of acute opportunistic infection (OI), the optimal timing of initiation of cART appears to vary somewhat based on the infective organism but in general terms should begin early, during the treatment of OI, but with enough time to allow some recovery from the specific OI.

In pregnant women, suppression of maternal viremia by the time of delivery is essential to reduce the risk of mother-to-child transmission. Other interventions that reduce this risk include elective caesarean section, intravenous zidovudine during labor, avoidance of breast feeding, and treatment of the newborn with zidovudine for 6 weeks post delivery.

As of 2010, at least 15 drugs from 6 different drug classes are available for commercial use. Combination antiretroviral therapy should include a minimum three drugs from at least two different drug classes aiming to provide the best tolerated, most durable, and least toxic regimen possible.

Once initiated, it is essential to continue monitoring patients regularly for potential drug toxicity, adherence and cART efficacy, immune reconstitution events and also non-AIDS events.

# Guidelines for the Treatment of HIV and AIDS in Resource-Limited Countries

Chris Duncombe • Deepti Suri

# 115

## Introduction

The World Health Organization (WHO) has been promoting a public-health approach for antiretroviral therapy (ART) to improve access in resource-poor settings. The public-health approaches for ART have been developed to support decentralized implementation in resource-poor countries. However, these guidelines have to be adapted according to local healthcare system.

In 2003, UNAIDS and WHO launched a global strategy, “3 by 5” initiative, to provide ART to three million people living with HIV/AIDS in 50 developing countries. This program was subsequently replaced by The Global Fund for AIDS, Tuberculosis, and Malaria as well as bilateral support like the President’s Emergency Plan for AIDS Relief (PEPFAR).

By the end of 2007, over 10 billion dollars had been donated and disbursed for the HIV pandemic in developing countries. WHO estimated that the number of people in low and middle-income countries who were receiving ART on July 2009 to be 4 million; however, an estimated 7 million eligible HIV-infected people were still in need of treatment.<sup>1</sup>

The development of generic medications has been an important advance in making ART available in resource-poor countries.<sup>2</sup> In Zambia, for example, 21,755 adults were enrolled into HIV treatment programs at 18 primary care facilities over 19 months.<sup>3</sup> In India, the National Aids Control Organization (NACO) is responsible for coordinating the overall response to HIV/AIDS, including that of the health sector, supported by the state AIDS control societies at the state level. The National AIDS Control Programme was launched in 1987, with the objective to reduce the transmission of HIV through a decentralized and comprehensive programme for generating awareness, changing behavior, targeting vulnerable groups, and conducting research. On November 30, 2003, the government announced a policy and programmed commitment to provide ART free of charge, with implementation starting on April 1, 2004. The availability of generic fixed drug combination regimen has revolutionized the management of these patients.

The guidelines given by WHO are the source documents used in the preparation of this chapter.

- *Antiretroviral Therapy for HIV Infection in Adults and Adolescents in Resource-Limited Settings: Towards Universal Access: Recommendations for a Public Health Approach (2006 revision)*. World Health Organization (Geneva).
- *Management of HIV infection and antiretroviral therapy in adults and adolescents: A clinical Manual*, 2007 World Health Organization, Regional Office for South-East Asia, Delhi.
- *Antiretrovirals for HIV: A Compilation of Facts and Product Information 2006*. World Health Organization, Regional Office for South-East Asia, Delhi.
- *Management of HIV Infection and Antiretroviral Therapy in Infants and Children. A Clinical Manual*, 2006. World Health Organization, Regional Office for South-East Asia, Delhi.

Management of HIV infection not only caters to the adults but also extends to children and pregnant women. In any developing country, health policies in relation to HIV need to have a holistic approach for its success. Issues in pediatric diagnosis and treatment, management of pregnant females, and drug resistance to antiretrovirals are dealt in this chapter.

Many HIV-infected people are unaware that they are infected with the virus. The key factor in success of management of HIV infection is early identification of HIV-infected individuals by screening which in turn would result in early access to life-saving treatment and help prevent the spread of the infection.

## HIV Testing

HIV voluntary counseling and testing (VCT) may utilize a **patient-initiated or provider-initiated approach**. Patient-initiated VCT is the process whereby a patient, who wants to know his/her HIV status, requests a HIV test. VCT should be part of routine care at health facilities that provide antenatal services, diagnosis, and treatment for tuberculosis and sexually

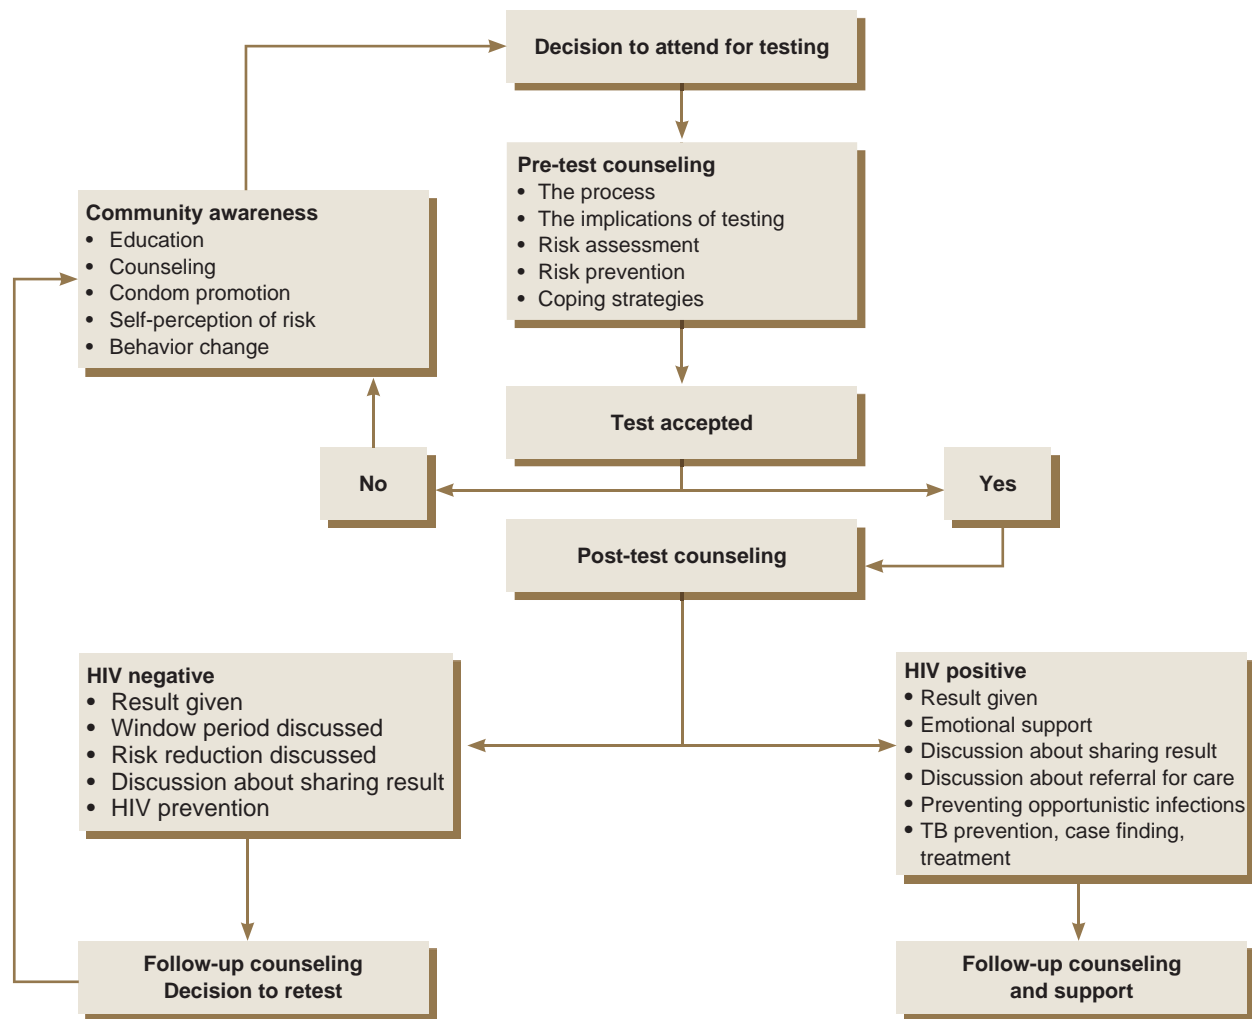

Fig. 115.1: HIV voluntary counseling and testing algorithm for adults and adolescents.

transmitted infections (Fig. 115.1). Provider-initiated HIV testing and counseling (PITC) is initiated by healthcare providers as part of all routine medical services. PITC has two main objectives; to confirm the HIV status of patients with suspected HIV-related symptoms, enabling medical services to be offered that would not be possible without knowledge of the HIV status of the person and to identify unrecognized HIV infection.

In an “opt-out” approach, patients may decline the HIV test if they do not want it to be performed. This approach may be suitable in situations where disclosure and discrimination may cause harm to the patient. An “opt-in” approach, where patients give consent to be tested rather than refusing a test, may be appropriate for vulnerable populations in some settings.

In an HIV-positive patient, the clinical signs and symptoms of HIV infection can be staged according to the established criteria. The WHO has given clinical and immunological staging of disease which could guide the physician in managing the patients (Annexure 1). Initiation of ART is guided according to the clinical as well as immunological staging.

## Initiating ART

### WHEN TO START ART IN ADULTS AND ADOLESCENTS

In resource-limited settings, ART is initiated based on clinical signs and symptoms, which are used to stage the severity of HIV disease using the WHO staging system. CD4 count is recommended prior to initiation of ART but its unavailability should not delay commencement of therapy. The precise time to start ART based on CD4 count is unknown but therapy should be started before CD4 count drops below 200 cells/ $\mu$ L. Pregnant women or patients with pulmonary tuberculosis with a CD4 count less than 350 cells/ $\mu$ L should also commence ART (Table 115.1).

### ASSESSMENT OF PATIENTS' READINESS FOR THERAPY

Managing patients on ART is complex due to the need for high rates of adherence to avoid the onset of drug resistance. This challenge is even more daunting in resource-poor nations where clinics are often understaffed and poorly funded.

**Table 115.1:** WHO's Clinical and Immunological Staging

Starting ART by clinical staging	
WHO Clinical Stage	Recommendation
1	Do not treat
2	Do not treat
3	<b>Treat</b>
4	<b>Treat</b>
Starting ART by CD4 count	
WHO Clinical Staging	CD4 testing available
1	Treat if CD4 cell count less than 200 cells/ $\mu$ L
2	
3	
	<ul style="list-style-type: none"> <li>Start ART before CD4 cell count drops below 200 cells/<math>\mu</math>L</li> <li>Start ART in pregnant women with WHO stage 3 or CD4 less than 350</li> <li>Start ART in patients with CD4 less than 350 and pulmonary TB (WHO stage 3) or severe bacterial disease</li> </ul>
4	Treat irrespective of CD4 count (Note: extrapulmonary TB is WHO stage 4)

However, it is imperative to inform the patient the need of lifelong ART.

- Build confidence and assess knowledge
- Explain ART and the objectives of the treatment
  - to avoid occurrence of OIs
  - to restore immunity
- Ensure the patient has understood
  - The treatment does not eliminate the virus
  - The treatment only suppresses the viral load
  - The treatment has to be taken regularly to avoid resistance
  - It is a lifelong treatment
- Advise and encourage the patient to disclose his diagnosis to his/her partner or family and support testing of the partner if status is unknown.

## ADHERENCE

The most common reason for ART failure is poor adherence.

- Treatment adherence should be strict and adherence to recommended regimens should be greater than 95% to avoid resistance.<sup>4</sup> This means that missing more than **3 doses per month** is associated with increased risk of drug resistance and failure
- Timing of drug intake is critical (drugs taken twice daily must be taken every 12 hours+/- one hour)
- Assessing readiness and commitment of patients for ART. Readiness to commence ART may be assessed by:
  - past ability to attend regular clinic visits and not miss appointments
  - past ability to take OI prophylaxis, such as cotrimoxazole
  - past ability to complete full course of TB therapy
  - adequate understanding

- If regular doses are missed or late, reinforce adherence counseling. Enlist community outreach teams and PLHA peer support groups as appropriate
- Treatment has to be continued for life
- Missed doses can be taken up to 6 hours in a BID regimen. If more than 6 hours late, skip dose and take next normal dose
- Drug side effects have to be understood and explained to the patient in advance of commencing ART
- People on ART need to continue to use condoms regularly and practice safe injecting use.

## RECOMMENDED AND ALTERNATIVE

### FIRST-LINE ANTIRETROVIRAL REGIMENS

Antiretroviral treatment regimens (Table 115.2) should have at least three active antiretroviral medications. Regimens are commonly discussed as having a “backbone” and a “base”. The backbone typically consists of two NRTIs. The base is either an NNRTI, or a PI. The available drugs and the formulations are compiled in Annexure 2.

## Antiretroviral Drug Toxicities

Side effects with ART are common; however, many side effects improve over time with continued administration. It is critically important for the clinician to differentiate between mild versus potentially serious adverse events when making decisions about continuing therapy. Some drug reactions are progressive with continued exposure and can be potentially life threatening. The patient must be counseled regarding these potentially serious adverse events and be told to stop therapy until the provider can evaluate them. However, frequent stoppage of drugs with prolonged “unstructured treatment interruptions” may promote resistance.

Details of the side effects and commonly implicated drugs and symptom directed toxicity management are summarized below in Tables 115.3 and 115.4.

## Cotrimoxazole Prophylaxis

Cotrimoxazole prophylaxis may be initiated in two different contexts.<sup>5</sup> “Classic” prophylaxis, where the target is the prevention of PCP and toxoplasmosis, is recommended for all HIV-infected adults with WHO stage 2, 3, and 4 HIV disease or with a CD4 count less than 200 cells/ $\mu$ L (if available). If the targets of prophylaxis are the reduction in morbidity and mortality associated with bacterial infections and malaria, in addition to the prevention of PCP and toxoplasmosis, cotrimoxazole is recommended for HIV

**Table 115.2:** WHO Recommended First-line and Alternative Antiretroviral Regimens

Regimen	Comments
<b>Preferred First-line regimens</b>	
<b>Zidovudine</b> + lamivudine + nevirapine or efavirenz	AZT may cause anemia and WHO recommends Hb monitoring. EFV is substituted for NVP intolerance and if patients are receiving rifampicin. Both NVP and EFV should be used with caution and careful monitoring in patients with known or suspected hepatic dysfunction. NVP should not be used in women with CD4 greater than 250 If EFV is not available, option in patients receiving rifampicin are NVP or a tripled nucleoside regimen (AZT + 3TC + abacavir) EFV may be used in women if they use consistent and reliable contraception EFV cannot be used in the first trimester of pregnancy but may be considered in the second and third trimester of pregnancy
<b>Tenofovir</b> + lamivudine + (nevirapine or efavirenz)	Calculation of creatinine clearance is recommended before initiating TDF and during TDF therapy. TDF is unavailable or expensive in many countries but this may change FTC is unavailable in many countries but this may change FTC/TDF co-formulation is available
<b>Alternative first-line regimens</b>	
<b>d4T</b> + lamivudine + nevirapine or efavirenz	d4T has significant toxicities (lipoatrophy, lactic acidosis, peripheral neuropathy) and careful clinical patient monitoring is recommended. WHO recommends that d4T should be phased out of treatment programs. d4T may continue to be used by many programs due to its availability and no requirements for laboratory monitoring.
<b>Abacavir</b> + lamivudine + nevirapine or efavirenz	Abacavir can cause a hypersensitivity reaction in some patients. This presents as constitutional signs and symptoms (including fever and rash) and abacavir should be stopped immediately and supportive therapy given. Rechallenge with abacavir following a hypersensitivity reaction can be fatal and should never be done. Abacavir is not commonly used in resource limited settings. It is expensive in most countries, although some generic versions are available

## Notes:

Emtricitabine (FTC) can be substituted for 3TC in any first-line regimen.

Lamivudine may be given as 300 mg OD. With tenofovir and efavirenz OD, this makes a convenient once/day regimen. AZT and nevirapine need to be dosed twice per day. Zidovudine 250 mg BID and 300 mg BID are both approved by WHO. Choice will depend on local availability.

**Table 115.3:** Antiretroviral Drug Toxicities

Time	Side effects and toxicities	Common drugs
Short term (the first few weeks)	Gastrointestinal toxicities nausea and vomiting, diarrhea	AZT, TDF, PIs
	Rash Most rashes occur within the first 2–3 weeks	NVP, EFV Abacavir PIs (rarely)
	Hepatotoxicity More common in hepatitis B or C co-infection	NVP, EFV PIs
	Drowsiness, dizziness, confusion, and vivid dreams Normally self-resolving but can take weeks to months	EFV
Medium term (the first few months)	Anemia and neutropenia	AZT
	Hyperpigmentation of skin, nails	AZT
	Lactic acidosis can occur at any time More common after the first few months Most commonly associated with d4T	d4T*, ddl, AZT
	Peripheral neuropathy can occur at any time More common after the first few months	d4T*,ddl
	Pancreatitis can occur at any time	ddl
Long term (after 6–18 months)	Lipodystrophy and lipoatrophy	d4T*, ddl, AZT, PIs
	Dyslipidemia	d4T*, EFV, PIs
	Diabetes	Indinavir
	Skin hair and nail abnormalities	PIs, especially Indinavir

\* Phasing out of d4T recommended by WHO.

Didanosine (ddl) and Protease inhibitors (PIs) are mostly used in second-line ART.

**Table 115.4:** Symptom Directed toxicity Management Recommendations

Toxicity	Causative ARVs	Recommendations
Acute pancreatitis	d4T* and ddI	Discontinue ART. Supportive treatment and laboratory monitoring. Resume ART with an NRTI with low pancreatic toxicity risk. (AZT, ABC, TDF)
Diarrhea	ddI (buffered formulation), LPV/r SQV/r	Usually self-limited, without need to discontinue ART. Symptomatic treatment should be offered.
Drug eruptions (mild to severe, including Stevens-Johnson syndrome or toxic epidermal necrolysis)	NVP, EFV (rarely)	In mild cases, antihistamines. Moderate rash, non-progressing and without mucosal involvement or systemic signs, consider a single NNRTI substitution (i.e., from NVP to EFV). In moderate and severe cases, discontinue ART and give supportive treatment. After resolution, resume ART with 3 NRTI or 2 NRTI + PI regimens.
Dyslipidemia, insulin resistance and hyperglycemia	PIs EFV	Consider replacing the suspected PI by drugs with less risk of metabolic toxicity
GI intolerance	All ARVs	Usually self-limited, without need to discontinue ART. Symptomatic treatment should be offered.
Hematological toxicities (particularly anemia and leukopenia)	AZT	If severe (Hb <6.5 g% and/or Absolute Neutrophil Count [ANC] <500 cells/ $\mu$ L) replace by an ARV with minimal or no bone marrow toxicity (e.g., d4T, ABC, or TDF) and consider blood transfusion.
Hepatitis	All ARVs (particularly with NVP and PI/r)	If ALT greater than 5-fold the basal level, discontinue ART and monitor. After resolution, replace the drug most likely associated.
Hyperbilirubinemia (indirect)	ATV	Generally asymptomatic, but can cause scleral icterus (without ALT elevations). Replace ATV for other PI.
Hypersensitivity reaction	ABC	Discontinue ABC and <b>do not restart</b> . Symptomatic treatment. Re-exposure may lead to a severe and potentially life-threatening reaction.
Lactic acidosis	All NRTIs (particularly d4T* and ddI)	Discontinue ART and give supportive treatment. After clinical resolution, resume ART, replacing the offending NRTI. ABC, TDF and 3TC are less likely to cause this type of toxicity.
Lipoatrophy and lipodystrophy	All NRTIs (particularly d4T*)	Early replacement of the suspected ARV drug (e.g., d4T* for TDF or ABC). Consider aesthetic treatment and physical exercises.
Neuropsychiatric changes	EFV	Usually self-limited, without need to discontinue ART.
Renal toxicity (nephrolithiasis)	IDV	If using IDV, interrupt IDV and offer hydration, laboratory monitoring and symptomatic treatment (50% recurrence rate). Consider replacing IDV for another PI.
Renal toxicity (renal tubular dysfunction)	TDF	Discontinue TDF and give supportive treatment. After clinical resolution, resume ART, replacing the offending drug.
Peripheral neuropathy	d4T* and ddI	Consider replacement by an NRTI with minimal or no neurotoxicity (AZT, TDF, or ABC). Symptomatic treatment should be considered.

\* Phasing out of d4T recommended by WHO.

infected adult with a CD4 count less than 350 cells/ $\mu$ L or with the same clinical criteria (WHO stage 2, 3, or 4) (Table 115.5).

### Immune Reconstitution Inflammatory Syndrome (IRIS)

The term “immune reconstitution inflammatory syndrome” (IRIS) describes a collection of inflammatory disorders associated with paradoxical worsening of preexisting infectious processes following the initiation of highly active antiretroviral therapy (HAART) in HIV-infected individuals. Preexisting infections in individuals with IRIS may have been previously diagnosed and treated or they may be subclinical and later unmasked by the host's regained

capacity to mount an inflammatory response. The clinical signs and symptoms and management principles are summarized in the Table 115.6.

### ART for Women of Childbearing Potential or Who are Pregnant

Decision to use antiretroviral agents to be used in women of child bearing age group depends on the medical need for ART for the women herself or as an antiretroviral prophylaxis to prevent transmission to the child (Table 115.7). ART is recommended for pregnant women according to the same eligibility criteria as for non-pregnant adults.

Women with WHO clinical stage 3 disease and CD4 count less than 350 cells/ $\mu$ L should initiate ART. EFV should be

**Table 115.5** Summary of Cotrimoxazole Prophylaxis in HIV Infected Adults

	CD4 not available	CD4 available*
When to commence primary cotrimoxazole prophylaxis	WHO clinical stage 2, 3, 4, (including all patients with TB)	Any WHO clinical stage and CD4 less than 200 cells/ $\mu$ L where the aim of cotrimoxazole prophylaxis is the prevention of PCP and toxoplasmosis. Any WHO clinical stage and CD4 less than 350 cells/ $\mu$ L where the aim of cotrimoxazole prophylaxis is the reduction of morbidity and mortality associated with malaria, bacterial diarrheal disease and bacterial pneumonias in addition to the prevention of PCP and toxoplasmosis
Commencing secondary cotrimoxazole prophylaxis	Secondary prophylaxis is recommended for all patients who have completed successful treatment for PCP	
Timing the initiation of cotrimoxazole in relation to initiating ART	Start cotrimoxazole prophylaxis first Start ART two weeks later if the individual is tolerating co-trimoxazole and has no symptoms of allergy (rash, hepatotoxicity) A two week separation will assist clinical management where the cause of the symptoms maybe either cotrimoxazole or ART (especially if starting nevirapine containing regimen)	
Dosing	One double strength tablet or two single strength tablets once daily Total daily dose is 960 mg (800 mg SMZ + 160 mg TMP)	
Cotrimoxazole in pregnant women	Women who fulfill the criteria for cotrimoxazole prophylaxis should continue on it throughout their pregnancy <sup>6</sup> If a woman requires cotrimoxazole prophylaxis during pregnancy, it should be started regardless of the stage of pregnancy <sup>7</sup> Breastfeeding women should continue to receive cotrimoxazole prophylaxis	
Patients allergic to sulpha-based medications	Dapsone 100 mg per day, if available Cotrimoxazole desensitization may be attempted but not in patients with a previous severe reaction to CTX or other sulpha containing drugs.	
Monitoring	No specific laboratory monitoring is required in patients receiving cotrimoxazole	
When to stop cotrimoxazole prophylaxis in patients on ART	CD4 count not available	CD4 count available
	<b>Option 1</b> Continue prophylaxis indefinitely <b>Option 2</b> Consider discontinuation in patients after one year on ART without WHO stage 2, 3 or 4 events, good adherence and secure access to ART	CD4 count greater than 200 or greater than 350 cells/ $\mu$ L, (depending on choice of CD4 starting level) for 6 months on ART <sup>8,9</sup>

\* Commence primary cotrimoxazole prophylaxis in the two situations described under the heading when CD4 available.

**Table 115.6** Clinical Features and Management of Immune Reconstitution Inflammatory Syndrome

Definition	A collection of signs and symptoms resulting from the ability to mount an immune response associated with immune recovery on ART. <sup>10</sup>
Frequency	10% of all patients initiating ART Up to 25% among patients initiating ART with a CD4 cell count less than 50 cells/ $\mu$ L. <sup>6,11,12</sup>
Timing	Typically within 2–12 weeks of initiation of ART but may present later
Signs and symptoms	Unexpected deterioration of clinical status soon after commencing ART Unmasking of subclinical infections such as TB, which present as new active disease Worsening of co-existing infections such a flare of hepatitis B or C
Most common IRIS events	60% of IRIS events are <i>M. tuberculosis</i> , MAC or cryptococcal disease <sup>13</sup>
Other reported IRIS events	Toxoplasmosis, cytomegalovirus, lymphoma, Herpes zoster and herpes simplex, human papilloma virus, molluscum contagiosum, psoriasis eczema, hepatitis B or C flare, sarcoidosis, Graves disease, Guillain-Barré Syndrome
Principles of Management	IRIS may be mild and resolve without treatment. Continue ART if possible Diagnose and treat the specific pathogen in order to decrease the antigen load. Consider corticosteroids in moderate to severe cases of IRIS. Prednisolone (or prednisone) at 0.5 mg/kg/day orally or IV for five to ten days or longer depending on the severity of the inflammation Discontinue ART and prioritize treatment of the pathogen in patients who are severely unwell Aspiration and drainage of lymph nodes and abscesses (may need to be repeated several times) Emergency surgical decompression in cases of tracheal or intestinal obstruction

discontinued and replaced with another drug as it is potentially teratogenic.

In other situations ART may be used as prophylaxis, when mother is not in need herself to prevent MCT and during breastfeeding.

## ART in Tuberculosis/HIV Co-infection

The intersection of the HIV and TB epidemics has led to a dramatic upsurge in global TB incidence, resulting in remarkable increase in morbidity and mortality in some

**Table 115.7** Initiating ART in Women during Pregnancy and Breastfeeding

Clinical Situation	Guiding principles	Recommendations
All women	Treatment decisions are based solely on the women's medical need	Recommended first-line regimen is a NVP-based plus 2 NRTIs. EFV plus 2 NRTIs may be used if women have access to consistent and reliable barrier methods of contraception or after the first trimester of pregnancy
Initiating ART in pregnant women	ART is recommended for pregnant women according to the same eligibility criteria as for non-pregnant adults Women with WHO clinical stage 3 disease and CD4 count less than 350 cells/mL should initiate ART	Recommended regimen is 2 NRTIs plus a NNRTI. The preferred regimen is AZT + 3TC + NVP with careful monitoring of women with higher CD4 counts (>250).
Women who are pregnant, are in the first trimester and are taking EFV	EFV should be discontinued and replaced with another drug	NVP is substituted for EFV with close monitoring in women with higher CD4 counts. Alternatively a PI-based or a triple NRTI regimen could be substituted
Women who are breastfeeding	ART is recommended for postpartum breastfeeding women who meet the WHO criteria for initiation of therapy for their own health	The preferred regimen is AZT + 3TC + NVP
Women who received ART as part of PMCT intervention	Women who have previously received single-dose NVP prophylaxis for prevention of MTCT should be considered eligible for NNRTI-based regimens. Alternatives may be considered for women whose exposure to single dose NVP (Sd-NVP) was <6 months before ART was initiated	Sd-NVP more than 6 months, NNRTI-based regimen. Sd-NVP <6 months, A triple NRTI regimen or PI-based regimen also can be considered

parts of the world. HIV-infected patients are at increased risk of developing active TB from both reactivated latent and exogenous infection. HIV infection is also a risk factor for accelerated progression of TB following exposure, which has resulted in outbreaks of multidrug-resistant and extensively drug-resistant (XDR) tuberculosis.

Initiating ART in patients with active TB is also guided by the CD4 count and is initiated at least 2 weeks after the initiation of treatment for tuberculosis as shown in Box 115.1. Choice of NRTI is the same as for all patients. Preferred NRTIs in first-line regimens are zidovudine or tenofovir. Alternatives are stavudine or abacavir. Efavirenz is the preferred NNRTI. Despite EFV blood levels being decreased in the presence of rifampicin, the standard 600 mg dose is recommended.<sup>14–18</sup> Patients receiving nevirapine-based ART should be switched to efavirenz while taking rifampicin. Switching back to NVP after

rifampicin is completed can be considered. When switching back from EFV to NVP no lead-in dose is required. If a pregnant woman develops active TB and she is in the second or third trimester, an EFV containing ART regimen can be considered. An alternative in women with active TB in the first trimester is a triple NRTI regimen or a NVP containing regimen, with careful monitoring in women with higher CD4 counts or when CD4 count is unknown.

### ART Failure and When to Switch Therapy

ART failure can be diagnosed on clinical, immunological or virological criteria (Table 115.8). In resource limited settings, viral load testing is often unavailable and clinical and/or immunological criteria are normally used. Failure is never defined in the first 6 months following initiation of ART. Clinical events that occur before the first 6 months of therapy often represent IRIS and not failure. ART failure necessitates change to second line or PI based regimen (Table 115.9). The second line ARVs are more toxic and warrant stringent monitoring. Table 115.10 summarizes common toxicities of second line agents and their management.

### Protease Inhibitor (PI) Component

A ritonavir-boosted PI (PI/r) is the backbone of all second-line regimens. WHO preferred PIs are:

- LPV/r (KALETRA®). New heat stable tablets (also marketed in resource limited countries as ALLUVIA®) are becoming increasingly available and do not require refrigeration
- ATV/r. ARV does not require refrigeration but require boosting with RTV which still needs refrigeration. Generic heat stable RTV tablets will become available soon

**Box 115.1** Initiating ART in Patients with Active TB

CD4 Cell Count	ART recommendations	Timing of ART in relation to the start of TB treatment
CD4 less than 200/ $\mu$ L	Recommend ART	Between 2 and 8 weeks
CD4 between 200 less than 350/ $\mu$ L	Recommend ART	After 8 weeks
CD4 greater 350/ $\mu$ L	Defer ART	Re-evaluate patient at 8 weeks and at the end of TB treatment
CD4 not available	Recommend ART	2–8 weeks

**Table 115.8:** Criteria for ART Failure

<b>Clinical failure</b>	New or recurrent WHO stage 4 condition after at least 6 months on ART
<b>Immunological failure</b>	<p><b>Pattern 1</b> CD4 count less than 100 cells/<math>\mu</math>L (some experts recommend <math>&lt;50</math> cells/<math>\mu</math>L) after one year of therapy</p> <p><b>Pattern 2</b> Return to or a fall below the pre-therapy CD4 baseline after one year of therapy</p> <p><b>Pattern 3</b> 50% decline from the on-treatment peak CD4 value (if known). CD4 cell count can also be used to determine when not to switch therapy. For example, in a patient with a new clinical stage 3 event for whom switch is being considered switching is not to be recommended if the CD4 cell count is greater than 200 cells/<math>\mu</math>L.</p>
<b>Virological failure</b>	Viral load greater than 10,000 copies/mL after at least 6 months on ART

**Table 115.9:** Choice of Second-Line Regimens for Treatment Failure<sup>19</sup>

First-line regimen		Second-line regimen	
		RTI component*	PI component
Preferred regimens	AZT + 3TC + (NVP or EFV)	TDF + 3TC	PI/r
	TDF + 3TC + (NVP or EFV)	AZT + 3TC	
Alternative regimen	d4T* + 3TC + (NVP or EFV)	TDF + 3TC	

\*The entire treatment regimen needs to be changed in the setting of treatment failure.

**Table 115.10:** Symptom Directed Toxicity Management for Second-Line ARVs

Toxicity	Causative ARVs	Recommendations
Dyslipidemia	PIs	Cholesterol and Triglyceride elevations to grade 1 or 2 Monitor, diet, exercise Cholesterol and Triglyceride elevations to grade 3 or 4 Treat elevated Triglycerides with fibrates (fenofibrate 600 mg 1–2 times per day) Treat elevated Cholesterol with statins. Avoid simvastatin due to interactions with PIs (Annexure 2)
GI intolerance	All ARVs	Usually self-limited, without need to discontinue ART. Symptomatic treatment should be offered.
Hematological toxicities (particularly anemia and leukopenia)	AZT	If severe (Hb $<6.5$ ), stop AZT and consider blood transfusion.
Hepatic dysfunction	LPV/r and other PIs less commonly	If ALT $>5$ -fold the basal level, discontinue ART and monitor. After resolution, try a different PI
Hyperbilirubinemia (indirect)	ATV	Generally asymptomatic, but can cause scleral icterus (without ALT elevations). Replace ATV or IDV with another PI.
Lactic acidosis	All NRTIs (particularly d4T* and ddI)	Discontinue ART and give supportive treatment. After clinical resolution, resume ART, replacing the offending ITRN. ABC, TDF, and 3TC are less likely to cause this type of toxicity.
Lipoatrophy and lipodystrophy	All NRTIs (particularly d4T*) and PIs	Early replacement of the suspected ARV drug.
Renal toxicity (renal tubular dysfunction)	TDF	Discontinue TDF and give supportive treatment. After clinical resolution, resume ART, replacing the offending drug.

\*Phasing out of d4T recommended by WHO.

Unboosted PIs are not recommended with the exception of NFV if no ritonavir is available. Nelfinavir is less potent than a boosted PI.<sup>20,21</sup> Second-line ARVs sometimes are more likely to produce serious side effects that need urgent attention.

## HIV Infection in Children

### LABORATORY DIAGNOSIS

#### Viral Diagnostic Assays

HIV infection can be definitively diagnosed using viral diagnostic assays (detection of HIV by DNA or RNA polymerase chain reaction [PCR]).<sup>22,23</sup> These assays may not be available in resource limited settings. If available, virological testing should be performed after 6–8 weeks in non-breastfed infants. In breastfed infants, testing should be performed between 6 weeks and 6 months to allow optimal infant feeding counseling, or 6 weeks after complete cessation of breastfeeding. HIV infection is diagnosed by two positive HIV virologic tests performed on separate blood samples.

#### HIV Antibody Testing

In the absence of viral diagnostic assays, HIV antibody testing is used. However, the diagnosis of HIV infection in infants and children by HIV antibody testing is complicated by the persistence of maternal antibodies in children up to 18 months of age. Breastfeeding infants are at risk of HIV infection during

the period of breastfeeding and a negative virologic or antibody test during the breastfeeding period does not exclude the child becoming infected at a later date. Testing is recommended at any time 6 weeks after complete cessation of breastfeeding. Two or more negative HIV antibody tests performed at age 9–12 months with an interval of at least 1 month between the tests also can be used to reasonably exclude HIV infection among non-breastfed children with no clinical evidence of HIV infection. HIV infection can be definitively excluded if the HIV antibody is negative at age 18 months. A persistent HIV positive test result after 18 months post delivery confirms HIV infection regardless of breastfeeding.<sup>24</sup>

### INFANT FEEDING COUNSELING<sup>25–28</sup>

- Explain risk of HIV transmission through breastfeeding and implications of mixed feeding. Specifically, explain that mixed feeding results in more HIV transmission than exclusive breastfeeding.
- Ensure mothers and family members understand the need to balance the competing risks of reducing the risk of HIV to infants through breastfeeding with the need for minimizing the risk of other causes of morbidity and mortality through not breastfeeding
- Provide counseling and information about the risks and benefits of various infant feeding options based on locally feasible and acceptable feeding practices
- Recommend avoidance of all breastfeeding if replacement feeding is acceptable, feasible, affordable, sustainable and safe. Otherwise, recommend exclusive breastfeeding during the first months of life and support mothers to safely use replacement feeding when it becomes feasible for them. It is always important to ensure that children less than six months who are not breastfed have uninterrupted access to nutritionally adequate breast-milk substitutes that are safely prepared.

### COTRIMOXAZOLE PROPHYLAXIS<sup>29</sup>

In resource-limited settings, cotrimoxazole prophylaxis is recommended for all HIV-exposed infants starting at 4–6 weeks of age (or at first encounter with the healthcare system) and continued until HIV infection can be excluded (Table 115.11). Cotrimoxazole is also recommended for HIV-exposed breastfeeding children of any age and cotrimoxazole prophylaxis should be continued until HIV infection can be excluded by HIV antibody testing (beyond 18 months of age or older) or virological testing (younger than 18 months of age) following at least six weeks after complete cessation of breastfeeding. The risk of PCP is greatest in the first 6 months of life. All children under one year of age with **documented** HIV infection should receive cotrimoxazole prophylaxis regardless of symptoms or CD4 percentage. Beyond the age of one year,

**Table 115.11:** Cotrimoxazole Prophylaxis for HIV-Exposed Infants and Children

HIV-exposed infants & children*	Situation		
	Confirmed HIV infected infants and children†		
	under 1 yr	1–4 yr‡	5 yr and older
<b>Cotrimoxazole prophylaxis is universally indicated, starting at four to six weeks after birth and maintained until cessation of risk of HIV transmission and exclusion of HIV infection.</b>	Cotrimoxazole prophylaxis is indicated regardless of CD4 percent or clinical status.	WHO stages 2, 3 and 4 regardless of CD4 percent OR Any WHO stage and CD4 less than 25%	Follow adult recommendations

**Universal option:** Prophylaxis for all infants and children born to confirmed or suspected HIV infected mothers. This strategy may be considered in settings with high prevalence of HIV, high infant mortality due to infectious diseases and limited health infrastructure.

\* Defined as a child born to an HIV-infected mother or child breastfeeding from an HIV-infected mother until HIV exposure stops (6 weeks after complete cessation of breastfeeding) and infection can be excluded

† In children under 18 months HIV infection can only be confirmed by virological testing.

‡ Once started on CTX it should continue until 5 years regardless of clinical symptoms or CD4 percentage. Specifically, infants who begin CTX prophylaxis before the age of one year and who subsequently are asymptomatic and/or have CD4 levels 25% or greater should remain on CTX prophylaxis until they reach 5 years of age.

initiation of cotrimoxazole prophylaxis is recommended for symptomatic children (WHO stages 2, 3, or 4) or children with CD4 less than 25%.<sup>30</sup> All children who commence cotrimoxazole prophylaxis (irrespective of whether cotrimoxazole was initiated in the first year of life or after that) should continue until the age of 5 years when they can be reassessed. Adult clinical staging and CD4 count thresholds for cotrimoxazole initiation or discontinuation apply for children older than five years of age.<sup>31</sup>

In children with **presumptive symptomatic** HIV disease, cotrimoxazole prophylaxis should be started at any age and continued until HIV infection status can be excluded.

### STARTING ART

The WHO clinical and immunological staging is given in Annexure 3. Initiation of ART is based both on the clinical as well as the immunological disease. The available pediatric drugs and formulations are given in Annexure 4.

Indications for initiating ART in infants and children

- WHO stage 3 or 4 in children with confirmed HIV infection.

**Box 115.2** WHO Recommended First-Line Antiretroviral Regimens for Children

- CD4 cell count suggestive of severe immunosuppression with confirmed HIV infection.
- WHO stage 3 or 4 and presumptive diagnosis of HIV infection in children younger than 18 months of age.

Recommended first-line ART regimens: Box 115.2.

**CHANGING THERAPY DUE TO CLINICAL FAILURE****Clinical Failure**

Clinical signs of drug failure in children include:

- lack of growth among children who show an initial response to treatment
- decline in growth among children who show an initial growth response to therapy
- a loss of neuro-developmental milestones or the development of encephalopathy
- occurrence of new opportunistic infections or malignancy signifying clinical disease progression (as distinguished from immune reconstitution syndrome, which can occur in the first three months following the initiation of ARV, and does not signify treatment failure).
- recurrence of infections, such as oral candidiasis, that are refractory to treatment

Before an ARV regimen is thought to be failing based on clinical criteria, the child should have had a reasonable trial on the therapy (e.g., have received the regimen for at least 24 weeks). Failure of therapy may be due to poor adherence.<sup>32,33</sup> Counsel to address adherence issues if this is the case and do not change the regimen.

**Immunological Failure**

Providing the child is adherent to the therapy, immunological failure is defined as a return in CD4 cell percent (or for children older than 6 years of age, absolute CD4 cell count) to pre-therapy baseline or below, in the absence of other concurrent infection to explain transient CD4 decrease, or a greater than 50% fall from peak level on therapy of CD4 cell percentage (or for children older than 6 years of age, absolute CD4 cell count) in the absence of other concurrent infection to explain transient CD4 decrease. A rapid CD4 decrease (greater than 30% over 6 months) also may indicate immunological failure. Change to second line antiretroviral therapy is recommended if the first line therapy has failed. PI based regimen with three NRTIs is recommended (Box 115.3).

**Box 115.3** Second-Line Treatment Regimen for Children

## Prevention of Mother-to-Child Transmission (PMCT)

### COUNSELING

Counseling is an essential part of PMCT programs to provide informed choice so that pregnant women are able to decide on:

- HIV testing
- Choosing ART treatment or ARV prophylaxis, with commitment to good adherence
- safe delivery options
- appropriate infant feeding practice

Another important aspect is that PMCT can be a useful means for HIV prevention as HIV-negative pregnant mothers can be thoroughly counseled to maintain their negative status, and their spouses should also be encouraged for testing.

### SAFE DELIVERY

Interventions that reduce MTCT risk in labor and delivery include:

- Universal precautions
- Minimal use of cervical examinations
- Avoidance of:
  - Prolonged labor
  - Routine rupture of membranes
  - Unnecessary trauma such as episiotomies and fetal scalp monitoring
- Minimize risk of postnatal hemorrhage
- Safe transfusion practices

Elective caesarean section, when performed before the onset of labor or membrane rupture, has been associated with reduced MTCT. But it needs to be considered individually, the benefits and risks of vaginal delivery versus elective caesarean section, including the safety of the blood supply and the risk of complications from operation.

### ARV PROPHYLAXIS FOR PMCT

ARV prophylaxis for prevention of MCT has been summarized in Table 115.12; refer Table 115.13 for doses of prophylactic ARVs.

### Conclusions

Predominant contribution to the global HIV comes from sub Saharan Africa and Central Asia and management of HIV infection in these resources limited settings, is a challenge. However, with universal access to HAART and effective healthcare programmers, control of HIV infection is now a realistic public health goal. Effective treatment guidelines for prevention of mother to child infection and universal management of individuals with HIV infection and their monitoring has successfully altered outcome in people living with HIV and AIDS. It is no longer a fatal disease but a chronic manageable condition.

**Table 115.12:** ARV Prophylaxis for Prevention of Mother-to-Child Transmission of HIV

Ranking	Time of administration		
	Pregnancy	Labor	Postpartum
<b>Recommended</b>	AZT (>28 weeks gestation)	Sd-NVP* + AZT/3TC	<b>Mother:</b> AZT/3TC × 7 days* <b>Infant:</b> Sd-NVP* + AZT × 7 days†
<b>Alternative</b>	AZT (>28 weeks gestation)	Sd-NVP	<b>Infant:</b> Sd-NVP + AZT × 7 days†
<b>Minimum</b>	-	Sd-NVP + AZT/3TC	<b>Mother:</b> AZT/3TC × 7 days <b>Infant:</b> Sd-NVP
<b>Minimum</b>	-	Sd-NVP	<b>Infant:</b> Sd-NVP

\*If the woman receives at least four weeks of AZT during pregnancy, omission of the NVP dose for mothers may be considered. In this case the NVP dose must be given to the infant immediately after birth, AZT is recommended for four weeks instead of one week, and the mother will not require 3TC during labor as well as AZT and 3TC postpartum.

†If the mother receives less than four weeks of AZT during pregnancy, AZT is recommended for four weeks instead of one week.

**Table 115.13:** Doses of Antiretroviral Prophylaxis Drugs for Prevention of Mother-to-Child Transmission

#### For Mothers

##### During pregnancy

- AZT 300 mg twice a day starting at 28 weeks or as soon as possible thereafter

##### During labor

- Sd-NVP 200 mg at onset of labor
- AZT 600 mg at onset of labor OR 300 mg at onset of labor and every 3 hours until delivery
- 3TC 150 mg at onset of labor and every 12 hours until delivery.

##### After delivery

- AZT 300 mg twice a day for 7 days
- 3TC 150 mg twice a day for 7 days

#### For Infants

- Sd-NVP: 2 mg/kg oral suspension (or 6 mg) at once immediately after birth (within 72 hours)
- AZT 4 mg/kg twice a day for 7 days OR 4 weeks\*
- 3TC 2 mg/kg twice a day for 7 days

\* If the mother receives less than four weeks of AZT during pregnancy, AZT is recommended for 4 weeks instead of one week.

## Annexures

### Annexure 1: WHO Clinical Staging of HIV Disease in Adults and Adolescents

The revised WHO clinical classification of HIV-associated disease is designed to be used in patients with **confirmed HIV infection**.

Along with CD4 count testing, where available, the staging system is used to guide decisions on when to start opportunistic infection (OI) prophylaxis and when to start and switch ART.

Clinical stage 1 (Asymptomatic)
Asymptomatic Persistent generalized lymphadenopathy
Clinical stage 2 (Mild disease)
Moderate unexplained weight loss (<10% of presumed or measured body weight) Recurrent respiratory tract infections (sinusitis, tonsillitis, otitis media, pharyngitis) Herpes zoster Angular cheilitis Recurrent oral ulceration Papular pruritic eruptions Seborrhoeic dermatitis Fungal nail infections
Clinical stage 3 (Moderate disease)
Unexplained severe weight loss (>10% of presumed or measured body weight) Unexplained chronic diarrhea for longer than one month Unexplained persistent fever (intermittent or constant for longer than one month) Persistent oral candidiasis Oral hairy leukoplakia Pulmonary tuberculosis Severe bacterial infections (e.g., pneumonia, empyema, pyomyositis, bone or joint infection, meningitis, bacteremia) Acute necrotizing ulcerative stomatitis, gingivitis or periodontitis Unexplained anemia (<8 g/dl), neutropenia (<0.5 × 10 <sup>9</sup> /L) and or chronic thrombocytopenia (<50 × 10 <sup>9</sup> /L <sup>3</sup> )
Clinical stage 4 (Severe disease)
HIV wasting syndrome <i>Pneumocystis jiroveci</i> pneumonia Recurrent severe bacterial pneumonia Chronic herpes simplex infection Oesophageal candidiasis (or candidiasis of trachea, bronchi, or lungs) Extrapulmonary tuberculosis Kaposi sarcoma Cytomegalovirus infection (retinitis or infection of other organs) Central nervous system toxoplasmosis HIV encephalopathy Extrapulmonary cryptococcosis including meningitis Disseminated non-tuberculous mycobacterial infection Progressive multifocal leukoencephalopathy Penicilliosis Chronic cryptosporidiosis Chronic isosporiasis Disseminated mycosis (extrapulmonary histoplasmosis, coccidiomycosis) Recurrent septicemia (including non-typhoidal <i>Salmonella</i> ) Lymphoma (cerebral or B cell non-Hodgkin) Invasive cervical carcinoma Atypical disseminated leishmaniasis Symptomatic HIV-associated nephropathy or HIV-associated cardiomyopathy

Source: Revised WHO Clinical Staging and Immunological Classification of HIV and case definition of HIV for surveillance, May 2006.

## Annexure 2: Dosages of Antiretroviral Drugs for Adults and Adolescents

Generic name	Dose	
<b>Nucleoside RTIs</b>		
Abacavir (ABC)	300 mg twice daily or 600 mg once daily	
Zidovudine (AZT)	250 mg or 300 mg twice daily	
Emtricitabine (FTC)	200 mg once daily	
Didanosine (ddI)	>60 kg: 400 mg once daily	
buffered tabs or enteric coated (EC) caps	<60 kg: 250 mg once daily	
Lamivudine (3TC)	150 mg twice daily or	
Stavudine (d4T)*	300 mg once daily	
	30 mg twice daily irrespective of weight	
<b>Nucleotide RTIs</b>		
Tenofovir	300 mg once daily	
	Creatinine clearance < 50 mL/min 300 mg alternate days	
<b>Non-nucleoside RTIs</b>		
Efavirenz (EFV)	600 mg once daily	
Nevirapine (NVP)	200 mg once daily for 14 days, followed by 200 mg twice daily	
<b>Proteases inhibitors</b>		
Atazanavir/ritonavir (ATV/r)	300 mg/100 mg once daily	
Indinavir/ritonavir (IDV/r)	800 mg/100 mg twice daily	
Lopinavir 133.3 mg + ritonavir 33.3 mg	Capsule	Three capsules twice daily (400/100mg twice daily)
		four capsules twice daily when combined with EFV or NVP (533/133,33 mg twice daily)
Lopinavir/ritonavir (LPV/r)	Tablet (heat stable formulation)	Treatment naïve patients
	Lopinavir 200 mg + ritonavir 50 mg	Two tablets twice daily irrespective of coadministration with EFV or NVP (400/100 mg twice daily)
		Treatment experienced patients
		Three tablets twice daily when combined with EFV or NVP (600/150 mg twice daily)

\* Phasing out of d4T recommended by WHO.

### Annexure 3: Revised WHO Clinical Staging of HIV/AIDS for Infants and Children with Established HIV Infection

The clinical staging system is designed for use where HIV infection is confirmed by HIV antibody or virological testing.

#### Primary HIV infection

Asymptomatic  
Acute retroviral syndrome

#### Clinical Stage 1

Asymptomatic  
Persistent generalized lymphadenopathy

#### Clinical Stage 2

Unexplained persistent hepatosplenomegaly  
Papular pruritic eruptions  
Extensive wart virus infection  
Extensive molluscum contagiosum  
Recurrent oral ulcerations  
Unexplained persistent parotid enlargement  
Linear gingival erythema  
Herpes zoster  
Recurrent or chronic upper respiratory tract infections (otitis media, otorrhea, sinusitis, tonsillitis )  
Fungal nail infections

#### Clinical Stage 3

Moderate unexplained malnutrition not adequately responding to standard therapy  
Unexplained persistent diarrhea (14 days or more )  
Unexplained persistent fever (above 37.5°C intermittent or constant, for longer than one month)  
Persistent oral candida (outside first 6–8 weeks of life)  
Oral hairy leukoplakia  
Acute necrotizing ulcerative gingivitis/periodontitis  
Lymph node TB  
Pulmonary tuberculosis  
Severe recurrent presumed bacterial pneumonia  
Symptomatic lymphoid interstitial pneumonitis  
Chronic HIV-associated lung disease including bronchiectasis  
Unexplained anemia (<8g/dl ), neutropenia (<500/mL) or chronic thrombocytopenia (<50 000/μL)  
HIV-associated cardiomyopathy or HIV-associated nephropathy

#### Clinical Stage 4

Unexplained severe wasting, stunting or severe malnutrition not responding to standard therapy  
Pneumocystis pneumonia  
Recurrent severe presumed bacterial infections  
(e.g., empyema, pyomyositis, bone or joint infection, meningitis, but excluding pneumonia)  
Chronic herpes simplex infection; (orolabial or cutaneous of more than one month's duration or visceral at any site)  
Extrapulmonary tuberculosis  
Kaposi sarcoma  
Oesophageal candidiasis (or candida of trachea, bronchi or lungs)  
Central nervous system toxoplasmosis (outside the neonatal period)  
HIV encephalopathy  
Cytomegalovirus (CMV) retinitis or CMV infection affecting another organ, with onset at age >1 month  
Extrapulmonary cryptococcosis including meningitis  
Disseminated endemic mycosis (extrapulmonary histoplasmosis, coccidiomycosis, penicilliosis)  
Chronic cryptosporidiosis  
Chronic isosporiasis  
Disseminated non-tuberculous mycobacterial infection  
Acquired HIV-associated rectal fistula  
Cerebral or B cell non-Hodgkin lymphoma  
Progressive multifocal leukoencephalopathy

## Annexure 4: Pediatric Drug Formulations and Doses of ARVs

Name of drug	Formulations	Pharmacokinetic data available	Age (weight), dose and dose frequency	Other comments
<b>Nucleoside analogue reverse transcriptase inhibitors</b>				
<b>Zidovudine (ZDV)</b>	Syrup: 10 mg/mL Capsules: 100 mg; 250 mg Tablet: 300 mg	All ages	<4 weeks: 4 mg/kg/dose twice daily 4 weeks to 13 yrs: 180 mg/m <sup>2</sup> /dose twice daily Maximum dose: ≥13 yrs: 300 mg/dose twice daily	Large volume of syrup not well tolerated in older children, Syrup needs storage in glass jars and is light sensitive Can give with food Doses of 600 mg/m <sup>2</sup> /dose per day required for HIV encephalopathy Capsule can be opened and contents dispersed or tablet crushed and contents mixed with small amount of water or food and immediately taken (solution is stable at room temperature) Do not use with d4T* (antagonistic antiretroviral effect)
<b>Lamivudine (3TC)</b>	Oral solution: 10 mg/mL Tablet: 150 mg	All ages	<30 days: 2 mg/kg/dose twice daily ≥30 days or <60 kg: 4 mg/kg/dose twice daily Maximum dose: >60 kg: 150 mg/dose twice daily	Well tolerated Can give with food Store solution at room temperature (use within one month of opening) Tablet can be crushed and contents mixed with small amount of water or food and immediately taken
<b>Fixed-dose combination of ZDV plus 3TC</b>	No liquid available Tablet: 300 mg ZDV plus 150 mg 3TC	Adolescents and adults	Maximum dose: >13 yrs or >60 kg: 1 tablet/dose twice daily (should not be given if <30 kg weight)	Ideally, tablet should not be split Tablet can be crushed if required and contents mixed with small amount of water or food and immediately taken At weight <30 kg, ZDV and 3TC cannot be dosed accurately in tablet form
<b>Stavudine (d4T)*</b>	Oral solution: 1 mg/mL Capsules: 15 mg, 20 mg, 30 mg, 40 mg	All ages	< 30 kg: 1 mg/kg/dose twice daily 30 to 60 kg: 30 mg/dose twice daily Maximum dose: > 60 kg: 40 mg/dose twice daily	Large volume of solution Keep solution refrigerated; stable for 30 days; must shake well. Needs to be stored in glass bottles. Capsules can be opened up and mixed with small amount of food or water (stable in solution for 24 hours if kept refrigerated) Do not use with ZDV (antagonistic antiretroviral effect)
<b>Fixed dose combination of d4T* plus 3TC</b>	No liquid available Tablet: d4T 30 mg plus 3TC 150 mg; d4T 40 mg plus 3TC 150 mg	Adolescents and adults	Maximum dose: 30–60 kg: one 30 mg d4T-based tablet twice daily ≥60 kg: one 40 mg d4T-based tablet twice daily	Ideally, tablet should not be split See comments under individual drug components
<b>Didanosine (ddI)</b>	Oral suspension pediatric powder/ water: 10 mg/mL. In many countries needs to be made up with additional antacid Chewable tablets: 25 mg; 50 mg; 100 mg; 150 mg; 200 mg Enteric-coated beadlets in capsules: 125 mg; 200 mg; 250 mg; 400 mg	All ages	< 3 mos: 50 mg/m <sup>2</sup> /dose twice daily 3 mos to < 13 yrs: 90–120 mg/m <sup>2</sup> /dose twice daily or 240 mg/m <sup>2</sup> /dose once daily Maximum dose: ≥13 yrs or > 60 kg: 200 mg/dose twice daily or 400 mg once daily	Keeps suspension refrigerated; stable for 30 days; must shake well Administer on empty stomach, at least 30 minutes before or 2 hours after eating If tablets dispersed in water, at least 2 of appropriate strength tablets should be dissolved for adequate buffering Enteric-coated beadlets in capsules can be opened and sprinkled on small amount of food

Name of drug	Formulations	Pharmacokinetic data available	Age (weight), dose and dose frequency	Other comments
<b>Abacavir (ABC)</b>	Oral solution: 20 mg/mL Tablet: 300 mg	Over age 3 months	<16 yrs or <37.5 kg: 8 mg/kg/dose twice daily Maximum dose: >16 yrs or ≥37.5 kg: 300 mg/dose twice daily	Can give with food Tablet can be crushed and contents mixed with small amount water or food and immediately ingested MUST WARN PARENTS ABOUT HYPERSENSITIVITY REACTION ABC should be stopped permanently if hypersensitivity reaction occurs
<b>Fixed-dose combination of ZDV plus 3TC plus ABC</b>	No liquid available Tablet: ZDV 300 mg plus 3TC 150 mg plus ABC 300 mg	Adolescents and adults	Maximum dose: > 40 kg: 1 tablet/dose twice daily	Ideally, tablet should not be split At weight <30 kg, ZDV/3TC/ABC cannot be dosed accurately in tablet form MUST WARN PARENTS ABOUT HYPERSENSITIVITY REACTION ZDV/3TC/ABC should be stopped permanently if hypersensitivity reaction occurs
<b>Non-nucleoside reverse transcriptase inhibitors</b>				
<b>Nevirapine (NVP)</b>	Oral suspension: 10 mg/mL Tablet: 200 mg	All ages	15–30 days: 5 mg/kg/dose once daily x 2 weeks, then 120 mg/m <sup>2</sup> /dose twice daily x 2 weeks, then 200 mg/m <sup>2</sup> /dose twice daily >30 days to 13 yrs: 120 mg/m <sup>2</sup> /dose once daily for 2 weeks, then 120–200 mg/m <sup>2</sup> /dose twice daily Maximum dose: >13 yrs: 200 mg/dose once daily for first 2 weeks, then 200 mg/dose twice daily	If rifampicin co-administration, avoid use (see Tuberculosis section) Store suspension at room temperature; must shake well Can give with food Tablets are scored and can be divided into two equal halves to give a 100 mg dose; can be crushed and combined with small amount of water or food and immediately administered MUST WARN PARENTS ABOUT RASH Do not escalate dose if rash occurs (if mild/moderate rash, hold drug; when rash cleared, restart dosing from beginning of dose escalation; if severe rash, discontinue drug) Drug interactions
<b>Efavirenz (EFV)</b>	Syrup: 30 mg/mL (note: syrup requires higher doses than capsules, see dosing chart) Capsules: 50 mg, 100 mg, 200 mg	Only for children over 3 yrs	Capsule (liquid ) dose for > 3 yrs: 10 to 15 kg: 200 mg (270 mg = 9 mL) once daily 15 to < 20 kg: 250 mg (300 mg = 10 mL) once daily 20 to < 25 kg: 300 mg (360 mg = 12 mL) once daily 25 to < 33 kg: 350 mg (450 mg = 15 mL) once daily 33 to < 40 kg: 400 mg (510 mg = 17 mL) once daily Maximum dose: ≥ 40 kg: 600 mg once daily	Capsules may be opened and added to food but have very peppery taste; however, can mix with sweet foods or jam to disguise taste Can give with food (but avoid after high fat meals which increase absorption by 50%) Best given at bedtime, especially in the first 2 weeks, to reduce central nervous system side effects Drug interactions
<b>Fixed-dose combination of *d4T plus 3TC plus NVP</b>	No liquid available Tablet: 30 mg d4T/150 mg 3TC/200 mg NVP; 40 mg d4T/150 mg 3TC/200 mg NVP	Adults and adolescents	Maximum dose: 30–60 kg: one 30 mg d4T-based tablet twice daily ≥60 kg: one 40 mg d4T-based tablet twice daily	Ideally, tablet should not be split At weight <30 kg, d4T/3TC/NVP cannot be dosed accurately in tablet form; if tablets are split, NVP dose will be inadequate for very young children and additional NVP is needed to give total of 200 mg/m <sup>2</sup> /dose twice daily Since it contains NVP, requires dose escalation See comments under individual drug components

Name of drug	Formulations	Pharmacokinetic data available	Age (weight), dose and dose frequency	Other comments
<b>Protease inhibitors</b>				
<b>Nelfinavir (NFV)</b>	Powder for oral suspension (mix with liquid): 200 mg per level teaspoon (50 mg per 1.25 mL scoop): 5 mL  Tablet: 250 mg (tablets can be halved; can be crushed and added to food or dissolved in water)	All ages  However, extensive pharmacokinetic variability in infants, with requirement for very high doses in infants < 1 yr	<1 yr: 50 mg/kg/dose three times daily or 75 mg/kg/dose twice daily >1 yr to <13 yrs: 55–65 mg/kg/dose twice daily  Maximum dose: ≥13 yrs: 1250 mg/dose twice daily	Powder is sweet, faintly bitter, but gritty and hard to dissolve; must be reconstituted immediately prior to administration in water, milk, formula, pudding, etc. – do not use acidic food or juice (increases bitter taste); solution stable for 6 hours  Because of difficulties with use of powder, use of crushed tablets preferred (even for infants) if appropriate dose can be given  Powder and tablets can be stored at room temperature  Take with food  Drug interactions (less than ritonavir-containing protease inhibitors)
<b>Lopinavir/ritonavir, (LPV/r)</b>	Oral solution: 80mg/mL Lopinavir plus 20 mg/mL ritonavir  Capsules: 133.3 mg Lopinavir plus 33.3 mg ritonavir	6 mo of age or older	> 6 mo to 13 yrs: 225 mg/m <sup>2</sup> LPV/57.5 mg/m <sup>2</sup> ritonavir twice daily or weight-based dosing: 7–15 kg: 12 mg/kg LPV/3 mg/kg ritonavir/dose twice daily 15–40 kg: 10 mg/kg lopinavir/5 mg/kg ritonavir twice daily  Maximum dose: > 40 kg: 400 mg LPV/100 mg ritonavir (3 capsules or 5 mL) twice daily	Preferably oral solution and capsules should be refrigerated; however, can store at room temperature up to 25°C (77°F) for 2 months; at temperature >25°C (77°F), drug degrades more rapidly  Liquid formulation has low volume but bitter taste  Capsules large  Capsules should <i>not</i> be crushed or opened, but must be swallowed whole  Should be taken with food  Drug interactions

\* Phasing out of d4T recommended by WHO.

## Introduction

Perinatal transmission is the most important route of human immunodeficiency virus (HIV) infection in children. Most of pediatric HIV infection is preventable by providing antiretroviral treatment and antiretroviral (ARV) prophylaxis interventions. Prevention of infection is critically important since perinatal HIV transmission is associated with rapid clinical progression in infancy. In 2008, in low- and middle-income countries, 1.4 million HIV-infected women gave birth and an estimated 430,000 children were newly infected with HIV.<sup>1</sup> One of the landmark achievements in HIV research has been the observations of Pediatric AIDS Clinical Trials Group 076 (PACTG 076), which demonstrated reduction in the risk of perinatal transmission by nearly 70% with ARVs.<sup>2</sup> Since then significant progress has been made in prevention of mother-to-child transmission (PMTCT) of HIV both in high-burden as well as in the resource-limited settings. Now, for the first time, the elimination of mother-to-child transmission (MTCT) of HIV is considered a realistic public health goal and an important part of the campaign to achieve the millennium development goals. “A generation of children free from HIV infection is not impossible.”

## Global Scenario

Before 1990, pediatric HIV infection was a uniformly fatal disease, and MTCT rates without any interventions were reported to be around 15–40%. The interim analysis of PACTG 076 trial demonstrated that in pregnant women a regimen consisting of zidovudine (ZDV) given antepartum and intrapartum to mother and to newborn for 6 weeks reduces the risk of maternal-infant HIV transmission by approximately two-thirds.<sup>3–5</sup>

After the success of the PACTG 076 trial,<sup>2</sup> in the next decade, various clinical trials were initiated to explore the development of shorter, less expensive prophylactic regimens more applicable to resource-limited settings. Taking into account that most transmissions occur during delivery and that *in utero* transmission predominantly occurs during the last two months of pregnancy<sup>6</sup> short-course ZDV prophylaxis regimens were designed. Combination ARV regimens were compared with

alternative, less expensive single drugs that could be used in simple regimens. Alternative prophylaxis regimens, like two-dose nevirapine prophylaxis given to mother during labor and to the child immediately after delivery, which had the advantage of being less expensive, ease of administration and effective were implemented in developing countries.

Today, global epidemiology of perinatal HIV depicts two distinct epidemics. Transmission which is reduced to less than 2% in resource-rich countries with implementation of recommendations for universal prenatal HIV counseling and testing, ARV prophylaxis, elective cesarean delivery and avoidance of breastfeeding.<sup>4,5</sup> Transmission rate as low as 0.5% in non-breast-feeding mothers who delivered at term while receiving ARV therapy with a plasma viral load less than 1500 copies/mL has been demonstrated.<sup>5,7,8</sup>

By contrast, the epidemic is strikingly different in resource-limited countries where majority of the HIV-infected women live. In these areas, the three-part, PACTG 076 zidovudine (ZDV) prophylaxis regimen is too complex and expensive for use. Even though effective, less complex and less expensive prophylaxis regimens have now been identified, ARV treatment may not be available to all. Limited maternal-child healthcare infrastructure has difficulty in supporting the addition of HIV counseling and testing and ARV prophylaxis programs; and breastfeeding remains a necessity for most infants. A major challenge is to bridge the gap in prevention of MTCT between resource-rich and resource-limited countries.

## Associated Risk Factors for Mother-to-Child Transmission of HIV (Table 116.1)

In the absence of preventive interventions, published MTCT rates for non-breastfeeding populations in industrialized countries range between 14% and 23%, while the rates in breastfeeding populations in resource-limited settings range between 25% and 48%.<sup>3</sup> With specific interventions in non-breastfeeding populations, the risk of MTCT can be reduced to less than 2%, and to 5% or less in breastfeeding populations.

HIV can be transmitted to the fetus as early as the first and second trimester of pregnancy. However, maternal transmission to the fetus occurs most commonly in the perinatal period. The risk of MTCT of HIV is multi-factorial; maternal plasma HIV RNA levels, mode of delivery and gestational age are independently associated with HIV transmission.<sup>9</sup> The associated risk factors are summarized in Table 116.1.

### IN UTERO TRANSMISSION

Studies have shown that MTCT can occur early in pregnancy, with HIV infection identified in fetuses as early as eight weeks of gestation.<sup>10</sup> HIV can infect the placenta directly and has been detected in fetal autopsy tissue during all three trimesters.<sup>10</sup> The virus is thought to spread cell-to-cell through the placenta, while another possible mechanism involves the passage of maternal mononuclear cells into the fetal circulation.<sup>10</sup> Factors that decrease the placenta's integrity like drug abuse, chorioamnionitis, have also been implicated in *in utero* transmission in the second and third trimester.<sup>10</sup>

### INTRAPARTUM TRANSMISSION

Up to 80% of MTCT is thought to occur during the intrapartum period, defined as the time period during labor and delivery. HIV is detected in cervicovaginal secretions of an infected woman.<sup>11</sup> Contact of infant skin and mucosa with cervicovaginal secretions

or blood or the duration of contact in the maternal genital tract are modifiable risk factors. Breakdown of maternal-fetal barrier followed by maternal-fetal microtransfusions through the placenta, mostly during the first stage of labor is also a proposed mechanism.<sup>12</sup>

Longer duration of rupture of maternal membranes, and thus more fetal contact with cervicovaginal secretions, has been associated with increased MTCT, with 2% increased transmission risk for every additional hour of ruptured membranes.<sup>13</sup> Two individual patient data meta-analyses showed that mode of delivery is not associated with a decreased risk of MTCT after the membrane rupture occurs.<sup>13</sup>

Although there is a large drive to decrease maternal serum viral load with ARV drugs as a means of decreasing MTCT, cervicovaginal HIV viral load and the response to ARV drugs do not always correlate with maternal serum viral load.<sup>11</sup>

### LATE POSTNATAL/BREASTFEEDING TRANSMISSION

Late postnatal breastfeeding transmission is defined as HIV infection in breastfed infants who seroconvert after 4 weeks of age with proof of negative HIV testing prior to 4 weeks of age. A randomized controlled trial in a resource-limited, breastfeeding population which showed that among all infants exposed to breast milk, breastfeeding transmission accounted for approximately 44% of infant HIV infections. The risk of HIV transmission through breast milk is of particular importance as most of the world's HIV-infected women live in areas where formula feeding is not affordable, feasible, available, sustainable, or safe. Increased risk of MTCT correlates with the duration of breastfeeding,<sup>14</sup> higher maternal breast milk viral loads and lower maternal CD4 counts,<sup>15</sup> maternal breast abnormalities such as cracked nipples or breast abscesses<sup>16</sup> and younger maternal age and higher parity.<sup>17</sup>

**Table 116.1:** Associated Risk Factors for Perinatal HIV Transmission

<b>Viral factors</b>	High viral load, Non-syncytium-inducing phenotype, HIV 1 disease
<b>Maternal factors</b>	Advanced disease (low CD4 count, symptoms of AIDS), Primary HIV infection of mother during pregnancy First of twins, Rupture of membranes more than four hours, Maternal bleeding, Mother not on ARV therapy, Vaginal delivery, Other sexually transmitted diseases,
<b>Fetoplacental factors</b>	Chorioamnionitis, Placenta previa, Prematurity (increased peripartum transmission)
<b>Infant factors:</b>	HLA concordance with mother
<b>Postnatal factors:</b>	Breastfeeding  Higher breast milk virus load, Mastitis or maternal nipple lesions, Maternal seroconversion during breastfeeding, Infant having thrush at less than six month age (in breastfeeding infant)

### Recent Guidelines for Prevention of MTCT

- 1. World Health Organization Guidelines (WHO):** ARV drugs for treating pregnant women and preventing HIV infection in infants Recommendations for a public health approach 2010.<sup>18</sup>
- 2. Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission:** Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-1 Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States.<sup>19</sup>

### Summary of Various Clinical Trials

Since the success of PACTG 076, various clinical trials have been conducted with the aim of finding more appropriate short, inexpensive treatment protocol. The overall results from these trials suggest that a number of different regimens have similar overall efficacy in preventing *in utero* and intrapartum

transmission, but that the efficacy of such regimens is diminished in breastfeeding populations due to the postnatal acquisition of HIV infection through breast milk. The trials are summarized in Table 116.2.

- A two-part antepartum/infant regimen can effectively reduce the risk of MTCT compared to no prophylaxis.

- A significant proportion of *in utero* transmission appears to occur between 28 and 36 weeks of gestation and is missed when antenatal therapy does not start until 36 weeks of gestation.
- The longer, three-part ZDV regimen is superior in preventing mother to child HIV transmission when it is feasible and affordable to administer such a regimen.

**Table 116.2:** Clinical Trials for Prevention of MTCT

Study	Drugs used during pregnancy	Antenatal and Intrapartum intervention	Postpartum intervention	Mode of infant feeding	Comments
PACTG 076/ANRS 024 trial, USA and France (Connor, 1994) <sup>2</sup>	AZT vs. placebo	Long (from 14 weeks); intravenous IP	Long (six weeks), infant only	Replacement feeding	8.3% in AZT arm vs. 25.5% in placebo arm at 18 months (68% efficacy)
CDC short-course AZT trial, Thailand (Shaffer, 1999) <sup>20</sup>	AZT vs. placebo	Short (from 36 weeks); oral IP	None	Replacement feeding	9.4% in AZT arm vs. 18.9% in placebo arm at 6 months (50% efficacy)
CDC short-course AZT trial, Côte d'Ivoire (Wiktor, 1999; Leroy, 2002) <sup>21</sup>	AZT vs. placebo	Short (from 36 weeks); oral IP	None	Breastfeeding (100%)	16.5% in AZT arm vs. 26.1% in placebo arm at 3 months (37% efficacy) 22.5% in AZT arm vs. 30.2% in placebo arm (26% efficacy) in pooled analysis at 24 months
<b>PETRA trial</b> , South Africa, Tanzania and Uganda (Petra, 2002) <sup>22</sup>	Antenatal, IP/PP AZT + 3TC vs. IP/PP AZT + 3TC vs. IP-only AZT + 3TC vs. placebo	Short (from 36 weeks); oral IP	Short (one week), mother and infant	Breastfeeding (74%, median duration 28 weeks) and replacement feeding	5.7% at six weeks for AP/IP/PP AZT + 3TC, 8.9% for IP/PP AZT + 3TC, 14.2% for IP-only AZT + 3TC and 15.3% for placebo (efficacy compared with placebo: 63%, 42% and 0%, respectively) 14.9% at 18 months for AP/IP/PP AZT + 3TC, 18.1% for IP/PP AZT + 3TC, 20.0% for IP-only AZT + 3TC and 22.2% for placebo (efficacy compared with placebo: 34%, 18% and 0%)
HIVNET 012 trial, Uganda (Jackson 2003) <sup>23</sup>	sd-NVP vs. AZT	Long (from 14 weeks); intravenous IP	Long (six weeks), infant only	Replacement feeding	11.8% in NVP arm vs. 20.0% in AZT arm (42% efficacy) at 6–8 weeks; 15.7% in NVP arm vs. 25.8% in AZT arm (41% efficacy) at 18 months
Perinatal HIV Prevention Trial (PHPT-1), Thailand (Lallemant, 2000) <sup>24</sup>	Four AZT regimens with different durations of AP and infant PP administration, no placebo	Long (from 28 weeks), short (from 36 weeks); oral IP	Long (for 6 weeks), short (for 3 days), infant only	Replacement feeding	Short-short arm stopped at interim analysis (10.5%); MTCT 6.5% in long-long arm vs. 4.7% in long-short arm and 8.6% in the short-long arm at 6 months (no statistical difference) in utero transmission significantly higher with short vs. long maternal therapy regimens (5.1% vs. 1.6%)
Perinatal HIV Prevention Trial (PHPT-2), Thailand (Lallemant, 2004) <sup>25</sup>	AZT alone vs. AZT + maternal and infant sd-NVP vs. AZT + maternal SD NVP	AZT from 28 weeks; oral IP: AZT alone or AZT + SD NVP	AZT for one week with or without SD NVP, infant only	Replacement feeding	AZT-alone arm was stopped due to higher MTCT than the NVP-NVP arm (6.3% vs. 1.1%); in arms in which the mother received SD NVP, MTCT rate did not differ significantly between the infant receiving or not receiving sd-NVP (2.0% vs. 2.8%)
DITRAME Plus (ANRS 1201.0) trial, Abidjan, Côte d'Ivoire (DITRAME 2005) <sup>26</sup>	Open label, AZT + SD NVP	AZT from 36 weeks; oral IP: AZT plus SD NVP	sd-NVP + AZT for one week, infant only	Breastfeeding (54%) and replacement feeding	6.5% (95% CI 3.9–9.1%) at six weeks; historical control group receiving short AZT only had MTCT 12.8% (98% breastfed in historical control group)
DITRAME Plus (ANRS 1201.1) trial, Abidjan, Côte d'Ivoire (DITRAME 2005) <sup>27</sup>	Open label, AZT + 3TC + SD NVP	AZT + 3TC from 32 weeks (stopped at 3 days PP); oral IP: AZT + 3TC + sd-NVP	sd-NVP + AZT for one week, infant only	Breastfeeding (66%) and replacement feeding	4.7% (95% CI 2.4–7.0%) at 6 weeks; historical control group receiving short AZT only had MTCT 12.8% (98% breastfed in historical control group)

Study	Drugs used during pregnancy	Antenatal and Intrapartum intervention	Postpartum intervention	Mode of infant feeding	Comments
Postnatal NVP + AZT trial, Malawi (Taha, 2004) <sup>28</sup>	Neonatal sd-NVP vs. sd-NVP + AZT	No AP ARV; oral IP: SD NVP	sd-NVP with or without AZT for one week, infant only	Breastfeeding (100%)	16.3% in NVP + AZT arm and 14.1% in sd-NVP only arm at 6–8 weeks (difference not statistically significant); MTCT rate at 6–8 weeks among infants who were HIV-uninfected at birth 6.5% and 16.9%, respectively
MASHI, Botswana (Thior, 2006) <sup>29</sup>	Initial: short-course AZT with/without maternal and infant sd-NVP and with/without breastfeeding Revised: short-course AZT + infant sd-NVP with/without maternal sd-NVP and with/without breastfeeding; women with CD4 <200/ $\mu$ L receive HAART	1st randomization AZT from 34 weeks ; oral IP: AZT + either sd-NVP vs. placebo	2nd randomization Breastfeeding + AZT (infant) 6 months + SD NVP, infant only Vs. Formula feeding + AZT (infant) 4 weeks + SD NVP, infant only	Randomization: 50% breastfeeding (median duration 5.8 months), 50% formula feeding	Initial design: In formula feeding arm, MTCT at 1 month 2.4% in maternal and infant sd-NVP arm and 8.3% in placebo arm ( $p = 0.05$ ); in breastfeeding + infant AZT arm, MTCT at 1 month 8.4% in sd-NVP arm and 4.1% in placebo arm (difference not statistically significant) Revised design: MTCT at 1 month 4.3% in maternal + infant sd-NVP arm and 3.7% in maternal placebo + infant sd-NVP arm (no significant difference; no interaction with mode of infant feeding) MTCT at 7 months 9.0% in breastfeeding + AZT arm and 5.6% in formula feeding arm; mortality at 7 months 4.9% breastfeeding + AZT vs. 9.3% formula feeding; HIV-free survival at 18 months 15.1% breastfeeding + AZT vs. 13.9% formula feeding

Abbreviations: AZT, zidovudine; NVP, nevirapine; sd-NVP, single dose nevirapine; IP, intrapartum; AP, antepartum; PP: postpartum.

- Incremental risk of postnatal infections was similar in the ZDV and placebo groups, suggesting that the ZDV benefit, while less in breastfeeding populations, is retained.
- Breast-feeding with extended ZDV prophylaxis was not as effective as formula feeding in preventing postnatal HIV transmission.
- Although HIV transmission was lower in the formula-fed infants, infant mortality at age 7 months was significantly higher in the formula feeding group; the primary causes of death were diarrhea and pneumonia. By age 18 months, HIV-free survival was similar in the two groups.<sup>28</sup>
- Relatively high morbidity and mortality associated with formula feeding in this resource-limited setting, but did not give definitive support to use of extended infant prophylaxis with ZDV to prevent postnatal HIV transmission.
- Alternative prophylaxis regimens, demonstrated that a single-dose intrapartum/newborn nevirapine regimen is superior to an ultra short intrapartum/postpartum ZDV regimen and appears equivalent to the intrapartum/postpartum ZDV/3TC PETRA regimen. Two-dose nevirapine prophylaxis regimen has the advantage of being less expensive, ease of administration, effective and could be implemented in developing countries.
- The latest study “The Kesho Bora study”<sup>30</sup> (a better future in Swahili) was conducted in five sites in Africa, enrolled women with a CD4 count between 200 and 500 cells/ $\mu$ L. The

randomized trial compared the triple-ARV regimen against a control regimen of zidovudine and single-dose nevirapine stopped at delivery as per WHO recommendations 2004. The triple-ARV regimen reduced HIV infections in infants by 43% compared with the control regimen, and reduced the risk of transmission during breastfeeding by more than half. This approach offered new hope for mothers with HIV infection who could not safely feed their babies with infant formula. It is suggested that this would improve the chances of infants remaining healthy and free of HIV infection as breast milk provides optimal nutrition and protects against other fatal childhood diseases such as pneumonia and diarrhea. There is no apparent risk to the health of mothers or their babies associated with the triple-ARV regimen compared with the control regimen. Findings from the Kesho Bora study have strongly influenced the new WHO guidelines on ARVs, prevention of mother-to-child transmission of HIV, and infant feeding.

### Obstetrical Counseling and Management of the HIV-Infected Woman

Care of the HIV-1-infected pregnant woman must involve an ongoing collaboration between the HIV specialist caring for the woman when she is not pregnant, her obstetrician, and the woman herself. The assessment should include evaluation of the following:

- (a) **General counseling related to prevention of perinatal transmission should include information about what is known about risk factors for transmission, particularly those potentially modifiable by the patient.** A long-term treatment plan should be developed with the patient and the importance of adherence to prescribed ARV regimens discussed. Decisions regarding initiation of ARV therapy in women not currently receiving therapy or to continue or alter treatment in women currently receiving therapy should be based on the same criteria as for non-pregnant individuals, with the additional consideration of the potential impact of such therapy on the fetus and infant.
- (b) Clinical assessment and the degree of existing immunodeficiency determined by CD4 cell count and percent. Initiate ART if required for mother's own health.
- (c) HIV-infected pregnant women should be monitored in the same fashion that non-pregnant individuals are monitored; closer monitoring may be warranted in women receiving combination ARV therapy. Measurement of CD4 cell count and HIV RNA levels approximately every trimester (every three to four months).
- (d) Assessment of the need for prophylaxis against *Pneumocystis jiroveci* pneumonia (PCP) or *Mycobacterium avium* complex (MAC), or for treatment of any current HIV-related illnesses. The criteria for initiation of PCP prophylaxis are the same as in non pregnant individuals. Trimethoprim-sulfamethoxazole (TMP/SMX) is the recommended prophylactic regimen. Because of theoretical concerns regarding potential for teratogenicity during the first trimester, aerosolized pentamidine may be considered as an alternative to TMP/SMX during this period due to its lack of systemic absorption.<sup>31</sup>
- (e) The criteria for initiation of chemoprophylaxis for MAC are the same as in non-pregnant individuals. Azithromycin is the drug of choice for prophylaxis of MAC in pregnant HIV-infected women as experience with rifabutin in pregnancy is limited and clarithromycin is teratogenic.
- (f) First trimester ultrasound is recommended for confirmation of gestational age and to guide potential timing of scheduled cesarean delivery if indicated. More intensive monitoring should be considered for the fetus when the mother is taking combination therapy, including assessment of fetal anatomy with ultrasound during the second trimester in women who have received combination ARV drugs in the first trimester (particularly efavirenz), because less is known about the effect of combination therapy on the fetus.
- (g) Screening for maternal syphilis infection as well as other sexually transmitted diseases is not only important in preventing congenital syphilis; one study demonstrated that maternal syphilis infection was associated with an increased risk of MTCT of HIV as well.
- (h) **Elective cesarean section:** Management of HIV-infected pregnant women during labor should focus on minimizing the risk for both perinatal transmission of HIV and

the potential for maternal and neonatal complications. Interventions that prevent infant exposure to infectious maternal blood and secretions in the birth canal during delivery could provide some protection against transmission. Cesarean delivery performed prior to labor would also prevent maternal-fetal microtransfusions that have been shown to occur during uterine contractions. A meta-analysis of 15 prospective cohort studies done to evaluate the relation between elective cesarean section and vertical transmission of human immunodeficiency virus type 1 (HIV-1), showed that of the 8533 mother-child pairs, after adjustment for receipt of ARV therapy, maternal stage of disease, and infant birth weight, the likelihood of vertical transmission of HIV-1 was decreased by approximately 50% with elective cesarean section, as compared with other modes of delivery (adjusted OR, 0.43; 95% CI, 0.33–0.56). The results were similar when the study population was limited to those with rupture of membranes shortly before delivery. The likelihood of transmission was reduced by approximately 87% with both elective cesarean section and receipt of ARV therapy during the prenatal, intrapartum, and neonatal periods, as compared with other modes of delivery and the absence of therapy (adjusted OR, 0.13; 95% CI, 0.09–0.19). Among mother-child pairs receiving ARV therapy during the prenatal, intrapartum, and neonatal periods, rates of vertical transmission were 2.0% among the 196 mothers who underwent elective cesarean section and 7.3% among the 1255 mothers with other modes of delivery.<sup>13</sup> In a review of 1982 patients, who were enrolled from January 1997 through May 2004 after the introduction of HAART, the rates of MTCT fell dramatically from 5% (1997–1998) to 1% (2001–2003). Among the subset of 560 women with undetectable HIV RNA levels, elective cesarean delivery was associated with a significant reduction in transmission risk compared with vaginal delivery or emergency cesarean section on univariate analysis (OR, 0.07; 95% CI 0.02–0.31). However, after adjustment for ARV therapy (none versus any), the effect was no longer statistically significant (adjusted OR 0.52, 95% CI 0.14–2.03,  $p = 0.36$ ).<sup>8</sup>

The American College of Obstetrics and Gynecology (ACOG) recommends that an opinion of elective cesarean delivery should be discussed and recommended for all HIV-infected pregnant women with viral loads above 1000 copies/mL. If the decision is made to perform an elective cesarean delivery, ACOG recommends it be done at 38 weeks gestation, due to the potential risk for labor and membrane rupture before the woman would reach 39 weeks gestation, which is the standard recommended time for operative deliveries in women without HIV infection.<sup>32</sup>

#### INTRAPARTUM PRECAUTIONS

- (a) A thorough review of maternal therapies should be done prior to administration of any drugs during labor to avoid any potentially adverse drug interactions. For example,

midazolam and ergot preparations should be avoided in women receiving protease inhibitors because their metabolism may be delayed by such ARV drugs.<sup>32</sup>

- (b) Because of the potential for increased postoperative maternal morbidity in HIV-infected women undergoing operative delivery, clinicians may opt to administer perioperative antibiotic prophylaxis.
- (c) Whenever possible, intrapartum management of HIV-infected women should minimize invasive procedures that might increase MTCT, such as fetal blood sampling, invasive fetal monitoring with procedures that may cause a break in the infant skin, (e.g., scalp electrodes), and artificial rupture of membranes.
- (d) The duration of membrane rupture is associated with increased risk of MTCT. Thus, in women who are not undergoing elective cesarean delivery, the interval between rupture of membranes and delivery should be minimized through augmenting labor, as needed.
- (e) Other ARV drugs should be continued on schedule during labor or preoperatively to provide maximal virologic effects and to minimize the risk of developing drug resistance.
- (f) Avoidance of episiotomy may decrease exposure of the infant to maternal blood. The infant should be washed before any blood is drawn, injections given, or other invasive procedures performed.

## POSTPARTUM EVALUATIONS

- (a) Maternal medical services during the postpartum period need to be coordinated between obstetric and HIV-specialist healthcare providers.
- (b) Comprehensive care and support services are required for infected women and their families. Comprehensive healthcare services should include HIV-related medical care, psychosocial support, and assistance with family planning and contraception.
- (c) Barrier methods of contraception are recommended to prevent HIV transmission and potential acquisition of HIV superinfection or other sexually transmitted diseases. If hormonal contraception is being considered, potential interaction with ARV and opportunistic infection prophylaxis drugs should be assessed. Several protease inhibitor and non-nucleoside reverse transcriptase inhibitor drugs as well as rifampin and rifabutin may lower hormonal levels and decrease contraceptive efficacy of oral hormones.

## REVISED PMTCT RECOMMENDATIONS

The 2010 revised PMTCT recommendations<sup>18</sup> are based on two key approaches (Fig. 116.1):

1. Lifelong ART for HIV-infected women in need of treatment for their own health, which is also safe and effective in reducing MTCT.
2. ARV prophylaxis to prevent MTCT during pregnancy, delivery, and breastfeeding for HIV-infected women not in need of treatment.

## HIV Infected Pregnant Women in Need for ART for their Own Health (Table 116.3)

The criteria for initiating ART for pregnant women are the same as for non-pregnant women. ART is recommended for all women who have CD4 cell counts of less than or equal to 350 cells/ $\mu$ L, irrespective of WHO clinical staging, and for all women in WHO clinical stage three or four, irrespective of the CD4 cell count. ART irrespective of gestational age should continue throughout pregnancy, delivery, during breastfeeding (if breastfeeding) and thereafter. It should be initiated as soon as the eligibility criteria are met. WHO recommends a non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimen as first-line ARV treatment regimen for infected individuals who need therapy in resource-limited settings in women, the NNRTI of choice is nevirapine.

The preferred first-line ART regimen in pregnancy comprises of an AZT + 3TC backbone combined with a non-nucleoside reverse transcriptase inhibitor (NNRTI): AZT + 3TC + NVP or AZT + 3TC + EFV. Alternative recommended regimens are TDF + 3TC (or FTC) + NVP and TDF + 3TC (or FTC) + EFV. EFV should not be started in the first trimester, and NVP should be used instead. EFV may be used in the second and third trimesters. The potential for life-threatening hepatic toxicity with chronic NVP therapy in women with CD4 cell counts over 250 cells/ $\mu$ L must also be borne in mind.

Maternal ART should be coupled with the daily administration of NVP or twice-daily AZT to infants from birth or as soon as feasible thereafter until 4–6 weeks of age, irrespective of the mode of feeding.

However, in resource-rich settings, ART is recommended for prevention of mother to child transmission in all pregnant women with HIV RNA levels greater than 1000 copies/mL, and is often used in women with lower RNA levels as well. A protease inhibitor-based HAART regimen can be substituted for prevention of mother to child transmission in women with higher CD4 counts.

## Antiretroviral (ARV) Prophylaxis to Prevent MTCT during Pregnancy, Delivery and Breastfeeding for HIV-Infected Women not in Need of Treatment (Table 116.3)

There are two available options for pregnant women not in need of ART themselves as per the WHO recommendations.

### Option A: AZT prophylaxis starting 14 weeks.

The maternal component of this ARV prophylaxis includes antepartum daily AZT plus single dose nevirapine at onset of labor plus zidovudine and stavudine during labor and delivery and for 7 days postpartum. Early initiation of maternal AZT in pregnancy, that is, starting at 14 weeks in order to further decrease the chance of *in utero* transmission and to limit missed opportunities of starting maternal prophylaxis. Consideration

**Table 116.3:** Antiretroviral Drugs for Treating Pregnant Women and Preventing HIV Infection in Infants**1. Antiretroviral therapy for HIV-infected pregnant women who need treatment for their own health****ARV eligibility criteria**

- All women with CD4 of  $\leq 350$  cells/ $\mu$ L, irrespective of clinical staging
- All women with clinical stage 3 or 4, irrespective of CD4 cell count

**When to start ART in pregnant women**

- As soon as feasible

**Recommended first-line regimens for pregnant women**

- AZT + 3TC + NVP or
- AZT + 3TC + EFV or
- TDF + 3TC (or FTC) + NVP
- TDF + 3TC (or FTC) + EFV

**Prophylaxis for infants born to pregnant women on ART**

All infants regardless of infant feeding mode

- NVP or AZT for 4–6 weeks

**2. Antiretroviral prophylaxis for pregnant women who do not need treatment for their own health****When to start ARV prophylaxis**

- As early as 14 weeks of pregnancy

**Prophylaxis regimens for the mother****Option A:**

- AZT during pregnancy plus
- sd-NVP + AZT + 3TC during labor and delivery plus
- AZT + 3TC for 7 days postpartum (may omit sd-NVP and AZT + 3TC if  $> 4$  weeks AZT)

**Option B:**

- AZT + 3TC + LPV/r or
- AZT + 3TC + ABC or
- AZT + 3TC + EFV or
- TDF + 3TC (or FTC) + EFV

Adapted from WHO Guidelines.<sup>18</sup>

can be given to omitting maternal intrapartum and postpartum sd-NVP and AZT + 3TC if the mother has been documented as receiving more than 4 weeks of AZT during pregnancy.

**Option B:** Triple ARV prophylaxis starting from 14 weeks of gestation.

The provision of maternal triple ARV prophylaxis during pregnancy in women who are not eligible for ART results in very low *in utero* and peripartum transmission rates. A high value is also placed on the simplicity of the intervention as it contains only one maternal and one infant regimen and may be available as a once-daily fixed-dose combination. The recommended maternal triple ARV regimens include AZT + 3TC + LPV/r; AZT + 3TC + ABC; AZT + 3TC + EFV; and TDF + 3TC (or FTC) + EFV. NVP-based regimens are not recommended because of the risk of hepatotoxicity for women with high CD4 counts ( $>350$  cells/ $\mu$ L). The same regimen is continued during labor and for 1 week after complete cessation of breastfeeding.

**CLINICAL SCENARIOS**

**HIV positive women in childbearing age group who wish to conceive:** The most important aspect of management involves

counseling. Effective and appropriate contraceptive methods should be provided as part of ART services wherever possible, in order to prevent unintended pregnancy, taking into consideration potential interactions of ARV drugs with hormonal contraceptives that could lower contraceptive efficacy.

Counseling before conception should cover the risk of infant HIV infection, risk factors and PMTCT, potential drug toxicity for mother and infant, safer sexual practices to prevent sexually transmitted infections (STIs), and other general health messages.

It is recommended that there be fully suppressive ART before conception and that it be maintained during pregnancy, labor, delivery and breastfeeding. Preferred ART regimens in such situations should have minimal teratogenic potentials for infants. Women who are planning to become pregnant should use a regimen that does not include EFV, in order to avoid the highest risk period of *in utero* EFV exposure (conception to day 28 of gestation).

**HIV positive women who are pregnant but treatment naïve:**

The first step in this situation is to assess the need of ART for the mother for her own health.

If the mother needs ART for her own health then triple drug therapy is initiated based on same criteria as for non-pregnant women. The primary benefit is the effective reduction in maternal HIV mortality and morbidity, and secondary benefits include the reduction in MTCT and the decrease in infant mortality at 12 months of age.

Recommendations for first-line ART in pregnant women take into account two specific concerns:

Increased NVP hepatotoxicity in women with higher CD4 counts and potential teratogenicity of EFV. While long term use of NVP is not recommended in women with CD4 counts greater than 350 cells/ $\mu$ L, there are conflicting data on whether there is an increased risk of hepatotoxicity with NVP in women with CD4 counts between 250 and 350 cells/ $\mu$ L. In the case of women who require ART for their own health, including pregnant women, it was felt that the benefits of using NVP outweighed the risks of not initiating ART. Close clinical monitoring (and laboratory monitoring, if feasible) during the first 12 weeks of therapy is recommended when NVP is initiated in women with a CD4 cell count of 250 to 350 cells/ $\mu$ L.

EFV should not be initiated in the first trimester of pregnancy but may be initiated in the second and third trimesters. There is low quality evidence of the risks of EFV causing neural tube defects. The rates of overall birth defects reported in association with EFV, NVP, LPV/r or TDF appear similar and are consistent with rates reported in congenital defects registries in general populations.

**HIV positive women who become pregnant while receiving ART:**

For women planning a pregnancy or who become pregnant while receiving ART, some additional considerations mainly include the choice of regimen based on gestational age, the clinical and laboratory findings, and the risk of MTCT. Known benefits and potential risks of ARV use during pregnancy (particularly during the first trimester) should be discussed with all women.

The interruption of treatment among eligible women receiving ART for their own health who have a good immune response to ART has been associated with viral rebound and renewed CD4 cell decline, increasing the risk of MTCT and HIV disease progression.<sup>33,34</sup> Discontinuing treatment before or during pregnancy is therefore not recommended.

For women receiving an EFV-based regimen and who plan to become pregnant, substitution of NVP in the place of EFV for at least the periconception period is recommended. Alternatively, a triple NRTI or PI-based regimen can be given. Some concerns exist about exposure to TDF *in utero* and the risks of abnormal fetal bone development. However, for women requiring ART and receiving TDF who become pregnant, the benefits of continuing treatment are likely to outweigh the theoretical risks of toxicity for the infant.

**HIV positive women on treatment and have had prior exposure to antiretrovirals for PMTCT:** Resistance to NNRTI drugs is an important concern for PMTCT regimens. The long half-life of NVP and its low genetic barrier to resistance means that detectable drug levels persist for 2–3 weeks in the presence of active viral replication following a single maternal dose.<sup>35–37</sup> EFV also has a long half-life, with detectable drug levels for more than 21 days following discontinuation.<sup>38</sup> This has clinical relevance in pregnancy where ARV drugs may be provided solely for prophylaxis against perinatal transmission and discontinued after delivery or after breastfeeding.

In a meta-analysis of 10 studies, the prevalence of NVP resistance in women 4–8 weeks following sd-NVP was 35.7%.<sup>39</sup> Additionally, NNRTI resistance can develop in women receiving NNRTI-based triple drug prophylaxis regimens following discontinuation of prophylaxis, particularly if all drugs are stopped simultaneously.<sup>40</sup> In most women, resistant virus can no longer be detected 6–12 months after exposure. However, low levels of viral resistance can persist for longer periods and in some cases can remain present in latently infected cells.<sup>41–43</sup>

Data suggest that women starting NNRTI-based ART within 6–24 months of sd-NVP exposure have higher rates of viral failure than those without sd-NVP exposure. A definite relationship between time from sd-NVP exposure to starting NNRTI-based ART has been observed but has varied between studies, with a significant improvement in response if there were more than 12 months between sd-NVP exposure and start of therapy.<sup>44–51</sup> A tail regimen for a minimum of 7 days is recommended following sd-NVP or cessation of NNRTI-based triple prophylaxis. The tail regimen is provided in order to suppress virus and prevent persistent single drug NNRTI exposure. Much lower NNRTI resistance rates of 0–7% at 2–6 weeks postpartum have been reported with the use of various tail regimens.<sup>52–57</sup>

The choice of ART regimen for pregnant women who require treatment for their own health but who have had exposure to ARV drugs for PMTCT prophylaxis in earlier pregnancies will therefore depend on the time since ARV PMTCT drug exposure at the time ART is being initiated, and whether a tail regimen was used for prevention of resistance following exposure to sd-NVP (given alone or in combination with other ARVs). As discussed

in the revised 2010 guidelines, ARV therapy for HIV infection in adults and adolescents,<sup>18</sup> viral load testing, if available, is particularly useful for monitoring response to treatment in this special situation.

A non-NNRTI-based ART regimen (e.g., a LPV/r-based regimen) is recommended for women who require ART for their own health who have received, within 12 months of initiating treatment, sd-NVP alone or in combination with other drugs without an NRTI tail. If a non-NNRTI-based regimen is not available, an NNRTI-based regimen may be started, but it is recommended that viral load testing (if available) be performed after 6 months of ART and, if the viral load is greater than 5000 copies/mL a switch to a boosted PI regimen (e.g., LPV/r) is recommended.

For women who have received sd-NVP alone or in combination with other drugs with a tail within 12 months of starting treatment, the initiation of a standard NNRTI-based ART regimen is recommended. Viral load testing (if available) is recommended after 6 months of ART and, if the viral load is greater than 5000 copies/mL a switch to a boosted PI regimen (e.g., LPV/r) is recommended.

For women who have received sd-NVP (alone or in combination with other drugs) more than 12 months before starting treatment (with or without a tail), a standard NNRTI-based ART regimen is recommended. As in the other scenarios above, if available, the viral load should be evaluated after 6 months of ART, and if greater than 5000 copies/mL a switch to a boosted PI regimen (e.g., LPV/r) is recommended.

In our own center, among 60 treatment-naïve HIV-1-infected patients, mutations were screened at codons 70 and 215 (conferring resistance to zidovudine) and at codon 184 (conferring resistance to lamivudine). Most of the patients showed a mixture of both wild-type and mutant virus. Mutant variants were observed in many patients, especially at codon 70 (48 patients [80%]) and codon 184 (19 patients [31.67%]). In contrast, the frequency of mutation at codon 215 was found to be very low (1 patient [1.67%]).<sup>58</sup> Thus, with increasing use of ARV drugs and previous exposure, individual tailoring of ART regimens may be required.

## Neonatal Monitoring

- A complete differential blood count should be performed as a baseline evaluation prior to administration of ZDV.
- Infants who have anemia at birth or who are premature warrant more intensive monitoring.
- Following completion of the ZDV prophylaxis regimen, all infants born to HIV-infected women should be placed on PCP prophylaxis at 6 weeks of age, unless there is adequate virologic test information to presumptively exclude HIV-1 infection. The preferred regimen is trimethoprim 150 mg/m<sup>2</sup>/day with sulfamethoxazole 750 mg/m<sup>2</sup>/day in divided doses two times a day and given three times per week on consecutive days. Prophylaxis is continued until at least age 12 months in all infants diagnosed as infected or whose infection status is not yet determined. After age 12

months, prophylaxis is continued only in infected children, depending upon their CD4 cell count. Prophylaxis is not recommended for infants who meet criteria for presumptive or definitive lack of evidence of HIV-1 infection.

## Non-antiretroviral Interventions to Reduce Perinatal HIV Transmission

A number of interventions to prevent perinatal HIV transmission that does not involve ARV drugs have been evaluated in the developing world. These include the following:

**Treatment/prophylaxis of malaria and sexually transmitted diseases:** Placental malaria was associated with increased risk of MTCT of HIV infection after adjustment for viral load in various studies.<sup>59</sup> There have not been any randomized trials to evaluate malaria chemoprophylaxis during pregnancy as a preventive strategy to reduce perinatal transmission in malaria-endemic locales. Given the availability of effective short-course ARV prophylaxis to reduce transmission, it is likely this question will need to be addressed through careful cohort studies.

Some studies have suggested that sexually transmitted diseases (e.g., gonorrhea, herpes simplex virus infection) may facilitate perinatal HIV transmission. Treatment of sexually transmitted infections might provide an effective intervention to decrease both sexual and perinatal HIV transmission.<sup>60,61</sup>

**Nutritional supplementation:** Multivitamin supplementation, but not vitamin A supplementation alone, was associated with significant improvement in non-HIV related pregnancy outcomes including fetal death (5.9 vs. 9.6% in the multivitamin versus placebo groups, respectively), low birth weight (8.8 vs. 15.8%), severe preterm birth at younger than 34 weeks (6.2 vs. 10.2%), and small for gestational age infants (10 vs. 17.6%) in a randomized controlled trial of 1075 pregnant women who, at 12–27 weeks of gestation, were assigned to placebo, vitamin A alone, multivitamins excluding vitamin A, or multivitamins including vitamin A; one-third were vitamin A deficient at baseline.<sup>62</sup>

**Vaginal virucidal cleansing:** While use of vaginal virucides does not appear to reduce perinatal HIV transmission, vaginal virucidal cleansing, like vitamin supplementation, is inexpensive, easily administered, does not require HIV testing for implementation, and is of potential overall benefit to infected and uninfected women

**Prophylaxis of chorioamnionitis:** Chorioamnionitis is associated with significant inflammation and activation of immune cells in the placenta, which could lead to breaks in the placental barrier, allowing passage of virus or infected lymphocytes from the mother to the fetus. However, data from a controlled clinical trial in Malawi and Zambia in which empiric therapy for chorioamnionitis with a short course of antibiotics was given to infected pregnant at 20–24 weeks gestation and again during delivery found that such therapy did not reduce perinatal HIV transmission or infant morbidity and mortality.<sup>63</sup>

**Breastfeeding and HIV infection:** Mother-to-child HIV transmission occurs *in utero*, peripartum, and postnatally via

breastfeeding; the risk of HIV transmission to the infant can be significantly reduced with ARV medications. Research on breast milk transmission is particularly critical since there are now effective short-course ARV prophylaxis regimens that can decrease *in utero* and intrapartum HIV transmission. In many resource-limited settings, replacement infant feeding is not safe, affordable, sustainable or culturally acceptable, and breastfeeding is the norm even among HIV-infected women.

- (a) Replacement feeding is recommended for infants born to HIV-infected mothers in the United States, which is the current standard of care in resource-rich settings. However, in developing countries, replacement feeding may be associated with greater infant morbidity and mortality from diarrheal disease, pneumonia, and other infectious diseases.
- (b) The risk of HIV transmission through breast milk is greatest in the first several months of life; however, a lower but constant risk persists throughout the entire breastfeeding period.
- (c) The risk of infant transmission increases with increased levels of maternal HIV RNA in plasma or breast milk.
- (d) ARV medications significantly decrease the risk of mother-to-child transmission of HIV during the antepartum, intrapartum, and early postpartum periods. However, an excess risk of HIV transmission occurs if ARV medications are discontinued during the breastfeeding period.
- (e) For HIV-infected mothers in resource-limited settings who are breastfeeding, postnatal ARV medications for the mother or infant during the breastfeeding period, rather than no drug intervention is recommended. The preferred interventional strategy will depend on the mother's CD4 cell count and HIV clinical status.
- (f) Among HIV-infected women with a CD4 cell count less than 350 cells/ $\mu$ L or with WHO stage 3 or 4 disease, antenatal combination ARV therapy should be started as soon as feasible, regardless of gestational age and continued for the lifetime of the woman. This strategy leads to decreased risk of maternal morbidity and mortality and a decreased risk of HIV transmission to the infant during breastfeeding.
- (g) For women with a CD4 cell count greater than 350 cells/ $\mu$ L and WHO stage 1 or 2 disease, either neonatal or maternal prophylaxis is a viable option to prevent infant HIV transmission. Both interventions should be continued during the entire period of breastfeeding and for one week beyond discontinuation. Standard ARV prophylaxis also needs to be offered for the prevention of mother-to-child transmission of HIV during the antepartum, intrapartum, and early postpartum periods.

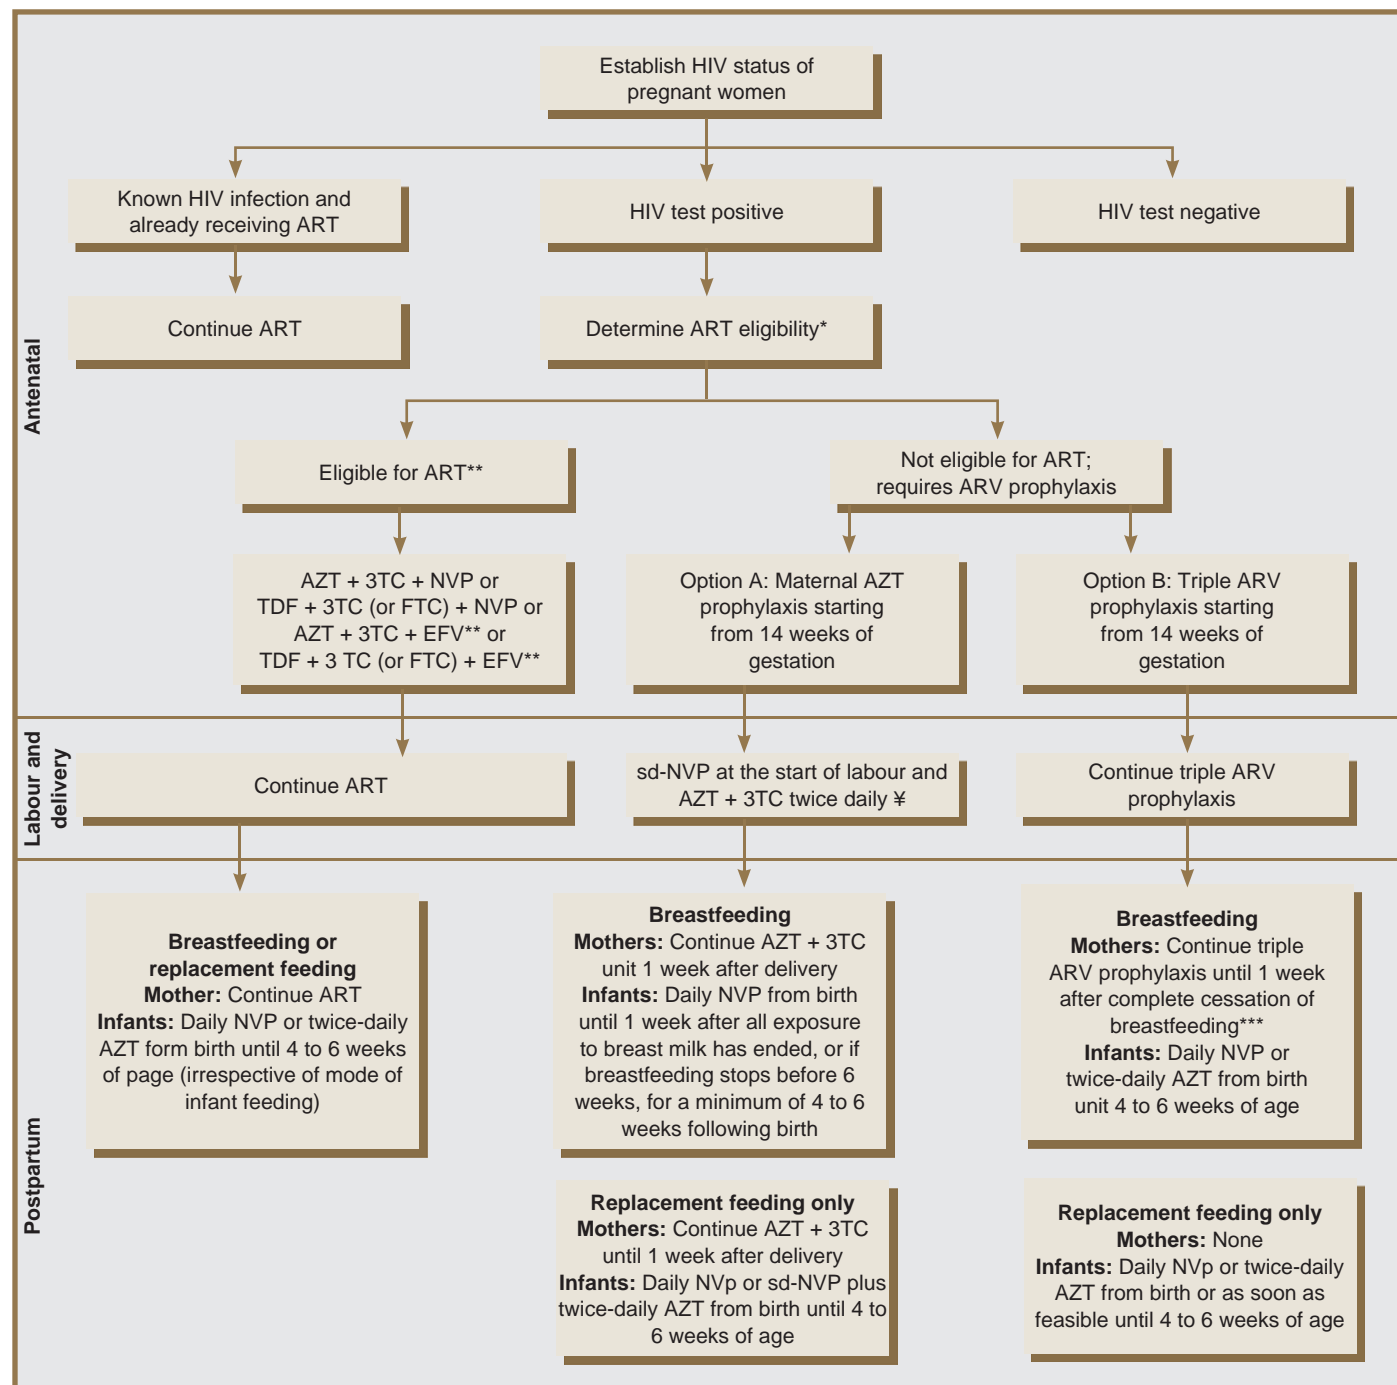

Exclusive breastfeeding, in combination with maternal or infant ART, is recommended for the first six months of life as it leads to nutritional and immunologic benefits for the infant. WHO recommends that national authorities should decide whether health services would principally counsel mothers to

either breastfeed and receive ARV interventions or avoid all breastfeeding, as the strategy that would most likely give infants the greatest chance of HIV-free survival. Where breastfeeding is judged to be the best option, exclusive breastfeeding for the first 6 months followed by introduction of appropriate complementary food thereafter must be emphasized. Breastfeeding may be continued for 12 months and gradually weaned within 1 month.

The postpartum guidelines of ARV drugs to be initiated along with breastfeeding are as summarized (Fig. 116.1).

In our own experience, most parents opt for replacement feeding than breastfeeding. With appropriate counseling and support, mothers are able to provide formula or cow's milk with spoon in a hygienic manner. The diarrheal infections noted are negligible. The clean hand practices, sterilization of utensils,

\*Start ARV prophylaxis while waiting to determine ART eligibility.

\*\*Avoid use of EFV in first trimester; use NVP instead.

\*\*\*When stopping any NNRTI-based regimen, stop the NNRTI first and continue the two NRTIs for 7 days and then stop them to reduce the chance of NNRTI resistance.

‡ If AZT was taken for at least the last 4 weeks before delivery, omission of the maternal sd-NVP and accompanying tail (AZT + 3TC) can be considered.

Fig. 116.1: Flowchart depicting the WHO recommendations for prevention of mother-to-child transmission.

boiling of milk need to be periodically emphasized during their routine as well as immunization visits.

## Indian Scenario<sup>1,64</sup>

The Prevention of Parent to Child Transmission of HIV/AIDS (PPTCT) program was started in the country in the year 2002 following a feasibility study in 11 major hospitals in the five high HIV prevalence states. Currently, there are more than 4000 Integrated Counseling and Testing Centers (ICTCs) in the country, most of these in government hospitals, which offer PPTCT services to pregnant women. Of these ICTCs, 502 are located in Obstetrics and Gynecology Departments and in Maternity Homes where the patient load predominantly comprises of pregnant women.

The Joint Technical Mission on PPTCT (2006) estimated that of 27 million annual pregnancies in India, 189,000 occur in HIV infected pregnant women. In the absence of any intervention, an estimated cohort of 56,700 infected babies will be born annually. The PPTCT programmed aims to prevent the perinatal transmission of HIV from an HIV infected pregnant mother to her newborn baby. The programmed entails counseling and testing of pregnant women in the ICTCs. Pregnant women who are found to have HIV infection are given a single dose of nevirapine at the time of labor; their newborn babies also get a single dose of nevirapine immediately after birth so as to prevent transmission of HIV from mother to child.

## Conclusions

International clinical trials have identified effective, simple, and less expensive ARV prophylaxis regimens more relevant to resource-limited countries. However, the availability of an effective intervention is only one of the several requirements for prevention of MTCT.

In order to access ARV prophylaxis, adequate systems of antenatal care are needed; however, on a global basis, one third of women lack prenatal care. Additionally, prenatal HIV counseling and testing are needed to identify HIV-infected women who could be offered effective prophylaxis. Yet, these services are not available in many resource-poor countries, and the cost of such programs has significantly contributed to the slow implementation of mother to child HIV transmission prevention programs. Additionally, in many resource-poor settings, postnatal transmission of HIV through breastfeeding remains a significant problem due to the lack of safe infant feeding alternatives.

It is increasingly recognized that programs to reduce mother to child HIV transmission must also consider the health of the mother. ARV prophylaxis regimens, while preventing HIV transmission to the infant, do not prevent progression of HIV disease and death in the mother. Studies have shown increased mortality in children whose mothers have died of HIV infection, even if the child is uninfected.

Additionally, provision of ARV therapy for HIV-infected individuals may be the most effective inducement for HIV

testing and decreasing the stigma of HIV, and hence increasing acceptance of prenatal testing by woman. The gap between the resource rich countries with negligible transmission with optimal antenatal care, HAART and replacement feeding and the developing countries needs to be bridged to have a generation of children free from AIDS.

### Summary

Perinatal transmission is the most important route of human immunodeficiency virus (HIV) infection in children. Significant reduction in the risk of perinatal transmission is possible with implementation of recommendations for universal prenatal HIV counseling and testing, and appropriate antiretroviral prophylaxis regimens. The first step is assessing the mother's need for antiretroviral therapy for her health, based on same criteria as for non-pregnant women. Triple-drug ART is recommended for all women who have CD4 cell counts of  $\leq 350$  cells/ $\mu$ L, irrespective of WHO clinical staging, and for all women in WHO clinical stage 3 or 4, irrespective of the CD4 cell count. ART irrespective of gestational age should continue throughout pregnancy, delivery, during breastfeeding (if breastfeeding) and thereafter. EFV should not be used in the first trimester due to potential teratogenicity. Prophylaxis regimens are recommended for mothers who do not need ART for their own health. These include AZT prophylaxis starting 14 weeks, sd-NVP + AZT + 3TC during labor and delivery plus AZT + 3TC for 7 days postpartum or triple ARV prophylaxis starting from 14 weeks of gestation. Triple-drug regimen is continued during labor and for 1 week after complete cessation of breastfeeding. Replacement feeding is recommended for infants born to HIV-infected mothers in the United States, which is the current standard of care in resource-rich settings. However, in developing countries, replacement feeding may be associated with greater infant morbidity and mortality from diarrheal disease, pneumonia, and other infectious diseases. For HIV-infected mothers in resource-limited settings who are breastfeeding, postnatal antiretroviral medications for the mother or infant during the breastfeeding period, rather than no drug intervention, is recommended.

# Guidelines for the Management of HIV-Associated Opportunistic Infections

Phillip J. Read

# 117

## Introduction

Opportunistic infections (OIs) represent an important cause of mortality and morbidity for those infected with HIV. Antiretroviral therapy (ART) as well as the judicious use of primary chemoprophylaxis, when available, has resulted in a large reduction in HIV-related deaths, and estimates of prognosis of people with HIV infection approach that of the non-infected population. However, access to ART is not universal, and not all HIV infected individuals taking treatment achieve immune reconstitution. These factors, combined with the problem of late-presentation of people with undiagnosed HIV means that clinicians are likely to be confronted by patients with HIV-associated OIs for many years to come.

There are several reference guidelines available to assist the clinician in the management of OIs. The specific presentations and diagnostic tools required to confirm or refute these diagnoses are too extensive to cover in this chapter, and readers are advised to refer to the relevant chapter in this book, or to review the full guidelines online.

This chapter provides information on the treatment of common OIs summarized from three highly regarded sources; the Centers for Disease Control and Prevention,<sup>1</sup> USA, the World Health Organisation (South East Asian Office),<sup>2</sup> and the Indian National AIDS Control Organisation/Ministry of Health & Family Welfare, India.<sup>3</sup> The website addresses for these guidelines are given in the reference section of this chapter. The availability and cost for each treatment will vary from country to country, so where possible the guidelines are compared, and preferred and alternative therapies listed to offer the broadest range of options to those working in resource-rich and resource-limited settings. Where available, information on the likely response to therapy and secondary prophylaxis is given, as well as key side-effects.

The question of when to commence ART after diagnosis and treatment of an OI is not fully resolved. A balance between triggering Immune Reconstitution Inflammatory Syndrome (IRIS) and the overlapping toxicities of several OI treatment regimens with ART must be balanced against the risk of further

HIV disease progression.<sup>4</sup> At this stage it is likely that the benefit of early initiation (within 2 weeks) of ART will depend not only on the specific OI, but also on the availability of resources to manage the complications of co-administration.

## Viral Opportunistic Infections

### CYTOMEGALOVIRUS (TABLE 117.1)

Prior to the advent of ART, cytomegalovirus retinitis was the most common ophthalmic OI, with a prevalence of around 30% in those with a CD4 count less than 50 cells/ $\mu$ L. Similarly, it may also cause colitis, esophagitis, encephalitis, and occasionally a pneumonitis.

### VARICELLA ZOSTER VIRUS (TABLE 117.2)

Although not necessarily AIDS-defining, varicella (herpes) zoster reactivation is 15–20 times more common in HIV positive individuals compared to the general population. It typically presents as a cutaneous disease, which may be multidermatomal, but may also cause retinal necrosis or encephalitis. Previously unexposed patients may be at risk of disseminated chicken pox.

### HERPES SIMPLEX VIRUS (TABLE 117.3)

Herpes simplex virus (HSV) infection of the oral or genital mucosa is extremely common in HIV positive individuals. Mild primary or recurrent episodes of herpes labialis or herpes genitalis can be managed similarly to the HIV negative population (see HSV management guidelines chapter). Suppressive HSV therapy may be required at either standard or increased dosage. The recommendations in the table below apply to severe mucocutaneous or visceral disease, and HSV encephalitis.

### HUMAN HERPES VIRUS-8 (KAPOSI SARCOMA HERPES VIRUS) (TABLE 117.4)

Kaposi sarcoma (KS) is the commonest AIDS-defining malignancy. Disease severity can be assessed using the T (extent of tumor) I (Immune status) S (severity of systemic illness) score. A good

**Table 117.1:** Recommendations for the Management of Cytomegalovirus Infection

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<p><b>Preferred: Retinitis</b> If sight-threatening— Ganciclovir intraocular implant + valganciclovir 900 mg PO 2 × daily for 2–3 weeks induction, then 900 mg PO 1 × daily until immune restoration Consider single dose intravitreal ganciclovir if implant likely to be delayed If peripheral lesions only— Valganciclovir 900 mg PO twice daily for 2–3 weeks followed by 900 mg once daily until immune restoration</p> <p><b>Alternative: Retinitis</b> Ganciclovir 5 mg/kg IV 2 × daily for 2–3 weeks followed by either ganciclovir 5 mg/kg IV daily or valganciclovir 900 mg PO daily Or Foscarnet 180 mg/kg IV in 2–3 divided doses for 2–3 weeks then 90–120 mg/kg IV daily Or Cidofovir 5 mg/kg IV weekly for 2 weeks, then 5 mg/kg every other week with saline hydration pre- and post treatment. Give probenecid 2 g PO 3 hours before therapy, and two further 1 g doses at 2 and 8 hours after therapy</p> <p><b>Preferred: Esophagitis, colitis, or pneumonitis</b> Ganciclovir IV or Foscarnet IV dosed as above for 21–28 days or until clinical resolution Or Valganciclovir 900 mg 2 × daily PO if absorption adequate</p> <p><b>Preferred: Neurological disease</b> Consider combination of ganciclovir IV and foscarnet IV followed by valganciclovir PO plus foscarnet IV until immune restoration</p>	<p>No specific guidance. Treat if drugs available. If not, commence ART</p>	<p><b>Preferred: All forms of disease</b> Ganciclovir 5 mg/kg IV 2 × daily for 2–3 weeks followed by oral ganciclovir capsules 1 g 3 × daily or ganciclovir IV once daily 5–7 days/week or valganciclovir 900 mg daily or Foscarnet IV 60 mg/kg 3 × daily or 90 mg/kg 2 × daily IV daily for 2–3 weeks then once daily maintenance Or Cidofovir IV weekly for 2 weeks with probenecid</p> <p><b>Alternative: Retinitis</b> Intravitreal injections: Ganciclovir 0.1 ml intravitreal injection at a dose of 200–4000 µg 3 × weekly for 2–3 weeks induction followed by weekly maintenance Or Foscarnet 1.2–2.4 mg twice weekly for 2–3 weeks followed by 1.2 mg weekly Or Cidofovir 20 µg weekly</p>

Intravitreal cidofovir not included in CDC guidelines due to risk of iritis, ocular hypotony and visual impairment.

Ganciclovir and valganciclovir may cause hematological abnormalities, in particular neutropenia.

Foscarnet and cidofovir are associated with renal and electrolyte disturbance.

CMV is a potential cause of IRIS, and close monitoring of retinal lesions after the institution of ART is recommended.

prognosis is possible if lesions are cutaneous only, if the CD4 count is more than 150 cells/µL and the absence of “B” symptoms. There may a dramatic response to ART, but cases of IRIS have also been described. Systemic therapy as an adjunct to ART is recommended where possible if there are greater than 25 cutaneous lesions, visceral involvement or edema, a failure to respond to other treatments or significant “B” symptoms. Adjunct treatment is rarely curative, and remission requires immune reconstitution.

**Human herpes virus-8** is also implicated in the etiology of primary effusion (body cavity) lymphoma and in multicentric Castleman disease.

The role of HHV-8 viral load monitoring in assessing response to therapy in HHV-8 related disease is an area of expanding research.

### JC VIRUS (PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY [PML]) (TABLE 117.5)

JC virus has been identified as the cause of PML, a condition with a poor prognosis even in the era of effective ART. Brain biopsy, although rarely necessary, provides a definitive diagnosis, but CSF examination may be positive for JC virus in 75–80% of cases, and MRI or CT scan of the head may show white matter disease. Diagnosis in the absence of these tests is usually clinical.

ART may be associated with improvement, but an inflammatory syndrome and worsening consequent to ART has also been described.

**Table 117.2:** Recommendations for the Management of Varicella Zoster Infection

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Treat within 1 week of rash Aciclovir 20 mg/kg up to 800 mg PO 5 × daily Or Valacyclovir 1 g PO 3 × daily Or Famciclovir 500 mg PO 3 × daily Duration: 5–7 days for varicella, and 7–10 days if shingles If severe or complicated varicella or extensive shingles: initiate with aciclovir 10–15 mg/kg IV 3 × daily for 7–10 days, switch to oral therapy to complete a 10–14 days course <b>Alternative:</b> Foscarnet 90 mg/kg IV 2 × daily if aciclovir resistance <b>Acute retinal necrosis:</b> Aciclovir 10 mg/kg IV 3 × daily for 10–14 days followed by valacyclovir 1 g PO 3 × daily for 6 weeks	<b>Preferred:</b> Local lesion care with gentian violet and chlorhexidine Treat if within 72 hours of rash Aciclovir 800 mg PO 5 × daily for 7 days. Consider famciclovir or valacyclovir if available Add aciclovir ointment every 4 hours topically if ophthalmic involvement.	<b>Preferred:</b> Treat within 3 days of rash Aciclovir 20 mg/kg PO up to maximum dose of 800 mg 4–5 × daily If extensive disease or visceral involvement, use acyclovir 10 mg/kg IV 3 × daily for 7–10 days until lesions and fever resolve. Consider switch to oral valacyclovir or famciclovir if no fever or visceral involvement Topical methylene blue or millian may combat superinfection

In addition to simple analgesics, pain relief may require gabapentin, amitriptyline, or opioids.

High-dose intravenous acyclovir may cause crystal nephropathy and renal impairment.

Antiviral therapy reduces the duration of lesions, and subsequent pain if started soon after symptoms.

**Table 117.3:** Recommendations for the Management of Herpes Simplex Infections

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Severe mucocutaneous infections— Initial therapy aciclovir 5 mg/kg IV 3 × daily Change to PO therapy after lesions regress <b>Preferred:</b> Aciclovir-resistant mucocutaneous infections— Foscarnet 80–120 mg/kg/day IV in 2–3 divided doses until clinical response <b>Preferred:</b> HSV encephalitis— Aciclovir 10 mg/kg IV q8h for 21 days	<b>Preferred:</b> Usually self-limiting and may not require treatment Care of the local lesion: Burow solution or gentian violet or chlorhexidine for 15 minutes 4–5 times/day plus aciclovir 200–400 mg 5 times daily for 7 days if available	<b>Preferred:</b> Aciclovir 400 mg 3 × daily for 7–14 days if disseminated mucocutaneous disease In severe infection or encephalitis: Aciclovir 5 mg/kg IV 3 × daily for 10 days

High-dose intravenous aciclovir may cause crystal nephropathy and renal impairment.

Topical cidofovir or trifluridine may be effective in aciclovir-resistant HSV.

Secondary prophylaxis post encephalitis may be useful.

Control of HSV ulceration may be important in HIV control.

HSV suppression has a very modest effect in reducing HIV viral load.

**Table 117.4:** Recommendations for the Management of Human Herpes Virus-8 (HHV-8)

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Initiate or optimize ART For visceral, disseminated cutaneous KS or primary effusion lymphoma, chemotherapy plus ART should be used Consider valganciclovir or ganciclovir as adjunct therapy For Multicentric Castleman disease: <b>Preferred:</b> Valganciclovir 900 mg PO 2 × daily or ganciclovir 5 mg/kg IV 2 × daily <b>Alternative:</b> Rituximab 375 mg/m <sup>2</sup> for 4–8 weeks	No specific recommendation. Start ART.	<b>Preferred for KS:</b> commence ART For facial local lesions consider: Liquid nitrogen cryotherapy Or Intralesional vinblastine Or Alpha-interferon Or Excision Consider adjunct therapy with Ganciclovir or Foscarnet or Cidofovir (no dose recommendations given)

For toxicities of ganciclovir, foscarnet, and cidofovir see Table 117.1.

Evidence for anti-herpes medications in this setting is lacking.

**Table 117.5:** Recommendations for the Management of PML

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> No specific treatment targeting JCV proven, initiate ART If worsening seen with ART and imaging suggests inflammatory component, consider corticosteroids	No specific recommendation	Commence ART

Although potentially active against JCV *in vitro*, antiviral medications such as cidofovir or ganciclovir have proven disappointing in clinical studies.

## Fungal Opportunistic Infections

### PNEUMOCYSTIS PNEUMONIA (TABLE 117.6)

Pneumocystis pneumonia (PCP) is caused by the fungus *Pneumocystis jirovecii*, an environmental organism. It is one of the most common OIs, and prior to ART affected over half of HIV-positive individuals at some point. Primary and secondary prophylaxis are important in disease prevention. Primary prophylaxis should be instituted in anyone with a CD4 count of less than 200 cells/ $\mu$ L, a CD4 percentage of less than 14%, or other AIDS conditions or signs of immunosuppression (such as persistent oral candidiasis). Early initiation of ART within the first two weeks has been shown to improve outcome.<sup>4</sup>

Cotrimoxazole (trimethoprim-sulfamethoxazole) commonly causes adverse event such as rash, fever and nausea. However it is

often possible to treat through these reactions using symptomatic management and careful observation of liver function.

### CANDIDIASIS (TABLE 117.7)

Candida species are common commensal organisms in immunocompetent and immunodeficient populations. Candida most frequently causes mucosal disease. Oropharyngeal or esophageal candidiasis represents likely progression of disease, but genital candidiasis is common at all CD4 strata. Most candida is of the *C. albicans* species, but other species such as *C. glabrata* or *C. tropicalis* may also be present, which may be less susceptible to topical azoles or oral fluconazole. Fluconazole-resistant *C. albicans* has also been described in patients on long-term suppressive therapy with recalcitrant disease. Disseminated candidiasis is relatively rare and not covered in this guideline, but may be

**Table 117.6:** Recommendations for the Management of PCP

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Trimethoprim-sulfamethoxazole 90–120 mg/kg/day in 3–4 divided doses for 21 days Intravenous if severe Oral if mild-moderate  <b>Alternative: Severe</b> Pentamidine 4 mg/kg IV once daily Or Primaquine 15–30 mg PO once daily plus clindamycin 600–900 mg IV q6-8h or clindamycin 300–450 mg PO q6-8h  <b>Alternative: Mild-moderate</b> Primaquine 15–30 mg PO once daily plus clindamycin 300–450 mg PO q6-8h Or dapsone 100 mg PO once daily plus trimethoprim 15 mg/kg/day in 3 divided doses Or Atovaquone 750 mg PO bid  <b>If PaO<sub>2</sub> &lt;70 mmHg on room air or Alveolar – arterial O<sub>2</sub> gradient (A-a gradient) &gt;35 mmHg</b> Prednisolone 40 mg PO bid day 1–5 40 mg PO once daily days 6–10 20 mg once daily days 11–21	<b>Preferred:</b> Trimethoprim-sulfamethoxazole 100 mg/kg/daily in 4 divided doses for 21 days. Intravenous if severe until well enough for oral.  <b>Oral dose:</b> 2 × 480 mg tablets 4 × daily if <40 kg 3 × 480 mg tablets 4 × daily if >40 kg  <b>Alternative:</b> Clindamycin 450 mg (oral) or 600 mg (IV) 3 × daily plus primaquine 15 mg PO once daily for 21 days  <b>If severe:</b> Prednisolone 20 mg 4 × daily with reducing dose of 7–10 days depending on response	<b>Preferred:</b> Trimethoprim-sulfamethoxazole 90–120 mg/kg/day in 3–4 divided doses for 21 days  <b>Oral dose:</b> 2 × Co-trimoxazole 960 mg tablets 3 × daily  <b>Alternative:</b> Trimethoprim 15 mg/kg/day PO plus dapsone 100mg daily Or Pentamidine 4 mg/kg IV once daily Or Clindamycin 600–900 mg IV q6-8h or 300–450 mg PO q6h plus primaquine 15–30 mg Or Atovaquone 750 mg bid PO  <b>If severe disease (PaO<sub>2</sub> &lt;70 mmHg or A-a gradient &gt;35 mmHg):</b> Prednisolone 40 mg bid for 5 days 40 mg once daily for 5 days 20 mg once daily until completion of treatment

All guidelines suggest steroids should be administered as soon as indicated, and certainly within the 1st 72 hours.

Improvement may not be noted for 3–5 days in some individuals and earlier treatment changes are not advised unless for toxicity.

Duration of therapy is recommended as 21 days for all regimens.

Secondary prophylaxis should follow treatment until immune restoration.

**Table 117.7:** Recommendations for the Management of Mucosal Candidiasis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
Oropharyngeal: <b>Preferred</b> (7–14 days): Fluconazole 100 mg PO daily Or Clotrimazole troches 10 mg PO 5 × daily Or Nystatin suspension 4–6 ml 4 × daily or 1–2 pastilles 4–5 × daily Or Miconazole mucoadhesive tablet PO daily <b>Alternative:</b> (7–14 days) Itraconazole solution 200 mg PO daily Or Posaconazole oral solution 400 mg 2 × daily for one day, then daily If fluconazole refractory, consider Amphotericin B oral suspension 100 mg/ml 1 ml PO 4 × daily Esophageal: <b>Preferred:</b> (14–21 days) Fluconazole 100 mg (up to 400 mg) PO or IV daily Or Itraconazole oral solution 200 mg PO daily Alternative, or if fluconazole refractory: (14–21 days) Voriconazole 200 mg PO or IV 2 × daily Or Posaconazole 400 mg PO 2 × daily Or Caspofungin 50 mg IV daily Or Micafungin 150 mg IV daily Or Anidulafungin 100 mg IV once, then 50 mg daily Or Amphotericin B 0.6 mg/kg IV daily	Oropharyngeal: (7 days) Nystatin pessaries 100,000 IU sucked every 4 hours Or Nystatin oral suspension 100,000 IU 3 × daily Or Amphotericin B oral suspension 1 spoon 3 × daily Or Miconazole 2% oral gel 2 spoons 3 × daily Esophageal: (14 days) Fluconazole 200 mg daily Or Itraconazole 400 mg daily Or Ketoconazole 200 mg daily	Oropharyngeal: (7–14 days) <b>Preferred:</b> Nystatin 500,000 IU tablet gargled 4–5 × daily Or Clotrimazole troche 10 mg 5 × daily Or Fluconazole 100–200 mg daily <b>Alternative:</b> Itraconazole 100 mg 2 × daily (up to 400 mg per day) Esophageal: (14–21 days) Fluconazole 200–400 mg PO daily Or Itraconazole 200 mg PO daily

Ketoconazole has a high rate of hepatitis and is not recommended unless no alternative available.

Amphotericin B oral suspension not available in USA.

Prolonged maintenance therapy not recommended due to development of resistance.

more common in those with indwelling vascular catheters, or who inject drugs, when candida endophthalmitis may co-exist.

### CRYPTOCOCCAL MENINGITIS (TABLE 117.8)

Cryptococcal meningitis is a common OI, manifesting typically in those with a CD4 count of less than 50 cells/ $\mu$ L, but the clinical signs may be initially subtle. Blood or tissue culture has a high sensitivity, as does serum or CSF cryptococcal antigen. Culture may be used to monitor response to treatment, with a switch to oral medications considered safe if negative at 2 weeks, but serial antigen determination does not predict treatment response. The major mortality and morbidity results from raised intracranial pressure. Serial lumbar puncture or CSF drainage may be necessary until pressures normalize.

If no clinical response occurs within 2 weeks of treatment then consideration should be given to either prolongation of the

current regimen if first line, optimizing drug dosage or switching to an alternative agent such as voriconazole if available. Resistance to amphotericin is rare.

IRIS associated with initiation of ART in patients previously treated for cryptococcal meningitis is particularly common, and may manifest months after treatment. Immediate initiation of ART in patients treated simultaneously with high fluconazole has been shown to be associated with toxicity and mortality. Most experts recommend waiting until stable on maintenance therapy.

### PENICILLIOSIS (TABLE 117.9)

*Penicillium marneffei* is rarely encountered outside the endemic regions of Northern Thailand, Vietnam, and Southern China. Response to initial treatment is usually good, but relapse occurs in 50% of patients without maintenance therapy unless

**Table 117.8:** Recommendations for the Management of Cryptococcal Meningitis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Induction 2 weeks Amphotericin B deoxycholate 0.7 mg/kg IV daily plus flucytosine 100 mg/kg PO daily in 4 divided doses for at least 2 weeks Or Liposomal amphotericin 4–6 mg/kg plus flucytosine if renal dysfunction present or likely <b>Alternative:</b> Amphotericin as above plus +/- Fluconazole 400 mg PO or IV daily Or Fluconazole 400–800 mg PO or IV plus flucytosine 100 mg/kg PO daily in 4 divided doses for 4–6 weeks if unable to tolerate amphotericin B <b>Preferred:</b> Consolidation Fluconazole 400 mg PO daily for 8 weeks followed by 200 mg daily until immune restoration <b>Alternative:</b> consolidation Itraconazole 200 mg 2 × daily for 8 weeks then 200 mg daily until immune restoration if intolerant of fluconazole	<b>Preferred:</b> Amphotericin B 0.7 mg/kg IV daily for 2 weeks followed by Itraconazole 200 mg 2 × daily or fluconazole 400 mg PO daily for 8 weeks <b>Alternative:</b> Fluconazole 400 mg daily for 8–12 weeks followed by Fluconazole 200 mg daily or Itraconazole 200 mg daily	<b>Preferred:</b> Amphotericin B 0.7 mg/kg/day IV plus Flucytosine 100mg/kg PO 4 × daily followed by Fluconazole 400 mg daily for 8–10 weeks, then 200 mg daily until immune restoration <b>Alternative:</b> Amphotericin B and Flucytosine as above followed by itraconazole 200 mg 2 × daily for 8 weeks Or Fluconazole 400 mg daily for 8 weeks followed by 200 mg daily Or Itraconazole 200 mg PO 3 × daily for 3 days, then 200 mg 2 × daily for 8 weeks Or Fluconazole 400 mg daily plus flucytosine 100 mg PO daily for 8 weeks

Addition of flucytosine is associated with quicker CSF sterilization and less chance of relapse.

Raised intracranial pressure should be actively managed by serial lumbar puncture or CSF shunt until normal.

Risk of IRIS with cryptococcal disease is high and may present several months after initiation of HIV therapy.

Where available and tolerated, fluconazole is preferred to itraconazole.

Amphotericin B may induce renal dysfunction.

Flucytosine can induce hepatitis and bone marrow suppression. Drug levels may be useful when available.

**Table 117.9:** Recommendations for the Management of Penicilliosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Acute infection in severely ill patients:</b> Amphotericin B deoxycholate 0.6 mg/kg/day IV daily for 2 weeks; followed by itraconazole 400 mg PO daily for 10 weeks <b>Mild disease:</b> Itraconazole 400 mg PO daily for 8 weeks <b>Maintenance therapy:</b> Itraconazole 200 mg PO daily	<b>Preferred:</b> Amphotericin B IV (0.7 mg/kg daily) for 2 weeks followed by itraconazole 400 mg orally daily for 8–10 weeks <b>If mild disease,</b> consider Itraconazole 400 mg daily for 8 weeks <b>Maintenance therapy:</b> Itraconazole 200 mg PO daily	<b>Preferred:</b> Moderate-to-severe cases: Amphotericin B 0.6 mg/kg/day × 2 weeks, then itraconazole 200 mg PO bid × 10 weeks <b>Maintenance therapy:</b> Itraconazole 200 mg daily

Fluconazole has less activity against *Penicillium marneffe* than itraconazole.

suppressive ART can maintain a CD4 of greater than 100 cells/ $\mu$ L for over 6 months. Cases of treatment failure may respond to voriconazole.

### ASPERGILLOSIS (TABLE 117.10)

Invasive aspergillosis, usually caused by *Aspergillus fumigatus* is rare, and occurs only in the very immunosuppressed, often after extensive courses of antibiotics and corticosteroids for other infections. Disease may be pulmonary or disseminated.

### HISTOPLASMOSIS (TABLE 117.11)

*Histoplasma capsulatum* infection affects as many as 5% of HIV infected persons living in an endemic area per year. The disease is most common in certain geographical areas of the Southern USA, and in Latin America, where risk factors such as contact with bird or bat droppings and heavy contact with soil should be avoided where possible in the immunosuppressed.

Clinical improvement on therapy should occur after 1 week, and blood or urine antigen titers may decrease thereafter. Treatment

**Table 117.10:** Recommendations for the Management of Aspergillosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Voriconazole 6 mg/kg IV 2 × daily for 1 day, then 4 mg/kg IV 2 × daily until clinical improvement followed by Voriconazole 200 mg PO daily  <b>Alternative:</b> Amphotericin B deoxycholate 1 mg/kg/day IV or Lipid formulation of amphotericin B 5 mg/kg/day IV or Caspofungin 70 mg IV × 1, then 50 mg IV daily or Posaconazole 400 mg 2 × daily PO	No specific recommendation	No specific recommendation

Relative paucity of data in the ART era.

Without immune reconstitution the prognosis is very poor.

failure may respond to posaconazole. Secondary prophylaxis should continue for at least one year, but may be stopped in a patient with a fully suppressed viral load on ART, with a CD4 cell count of greater than 150 cells/ $\mu$ L and no signs of ongoing disease. However, because relapse is common, some recommend lifelong secondary prophylaxis.

### Coccidioidomycosis (Table 117.12)

This disease, endemic to the Southwest USA and some areas of Central and Latin America responds slowly to treatment. Relapse is common and secondary prophylaxis should be maintained for life.

## Protozoal Opportunistic Infections

### Toxoplasma Gondii (Table 117.13)

Cerebral toxoplasmosis usually results from reactivation of latent toxoplasma cysts, but may also result from primary infection. It is the commonest cause of cerebral lesions in an HIV positive patient. Treatment should be instituted empirically, and

**Table 117.11:** Recommendations for the Treatment of Histoplasmosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Moderate to severe Liposomal amphotericin B 3 mg/kg IV daily for 2 weeks followed by itraconazole 200 mg PO 3 × daily for 3 days then 200 mg 2 × daily  <b>Alternative:</b> moderate to severe Amphotericin B deoxycholate 0.7 mg/kg IV daily or Amphotericin B lipid complex 5 mg/kg for 2 weeks followed by itraconazole as above  <b>Preferred:</b> less severe disease Itraconazole 200 mg 3 × daily for 3 days then 2 × daily  <b>Preferred:</b> Meningitis Liposomal amphotericin 5 mg/kg daily for 4–6 weeks followed by itraconazole 200 mg 2–3 × daily	Amphotericin B 0.7 mg/kg IV daily. Minimum total dose should be 2 g. Followed by itraconazole 200 mg daily for life or until immune recovery on ART	Amphotericin B 0.6 mg/kg IV daily for 2 weeks then itraconazole 200 mg PO 2 × daily for 10 weeks followed by 200 mg daily for life

Itraconazole levels may be useful if available.

Ideally Itraconazole maintenance should continue for at least 12 months and only discontinued after immune restoration.

Itraconazole solution may be better absorbed than capsules.

**Table 117.12:** Recommendations for the Management of Coccidioidomycosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> mild disease Fluconazole 400 mg PO daily Or Itraconazole 200 mg PO 3 × daily for 3 days then 2 × daily  <b>Preferred:</b> severe, non-meningeal Amphotericin B 0.7–1.0 mg/kg IV daily Or Lipid formulation Amphotericin 4–6 mg/kg IV daily Switch to azole when clinically improved  <b>Preferred:</b> Meningeal disease Fluconazole 400–800 mg PO or IV daily  <b>Maintenance:</b> Fluconazole 400 mg PO once daily Or Itraconazole 200 mg PO 2 × daily	No recommendation	No recommendation

Meningitis may cause raised intracranial pressure.

Maintenance therapy as secondary prophylaxis should be life long.

**Table 117.13:** Recommendations for the Management of Cerebral Toxoplasmosis Infection

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Pyrimethamine 200 mg PO loading dose, then 50 mg (<60 kg) or 75 mg (>60 kg) PO daily plus sulfadiazine 1000 mg (<60 kg) or 1500 mg (>60 kg) PO q6h plus leucovorin 10–25 mg PO daily <b>Duration:</b> 6 weeks or longer if response incomplete <b>Alternative:</b> Clindamycin 600 mg IV or PO q6h plus pyrimethamine/leucovorin as above Or Trimethoprim-sulfamethoxazole 5/25 mg/kg IV or PO 2 × daily Or Atovaquone 1500 mg 2 × daily with or without either or sulfadiazine 1000–1500 mg PO q6h or Azithromycin 900–1200 mg PO daily plus pyrimethamine/leucovorin as above	<b>Preferred:</b> Pyrimethamine 75–100 mg loading dose then 25–50 mg daily plus sulfadiazine 1000 mg q6h plus folic acid 15 mg alt days. <b>Duration:</b> 6 weeks	<b>Preferred:</b> Pyrimethamine 100–200 mg PO loading dose, then 50–100 mg daily plus folinic (or folic) acid 10 mg PO daily plus sulfadiazine 1000–2000 mg 4 × daily <b>Alternative:</b> Trimethoprim-sulfamethoxazole 5/25 mg/kg daily Or Clindamycin 600 mg 3 × daily plus pyrimethamine 100 mg PO loading dose followed by 50 mg PO daily plus folinic acid 10 mg PO daily

Anticonvulsants are not necessary unless history of seizures.

Steroids (e.g., dexamethasone) may be indicated to reduce mass effect from focal lesions.

Renal impairment common with sulfadiazine; ensure adequate fluid intake.

Treatment duration 6 weeks.

Secondary prophylaxis should follow treatment until immune restoration.

further investigations performed if good clinical or radiological response does not occur within the first 2 weeks of therapy. Both clindamycin and sulfadiazine can cause rash or hepatitis, and switching to alternative regimen is recommended if these symptoms persist. Sulfadiazine may crystallize in the urine and cause renal impairment; hence urine output should be greater than 1500 ml/day. Pyrimethamine causes myelosuppression through inhibition of folic acid synthesis. The addition of folinic acid to pyrimethamine-based regimens is therefore essential.

Primary prophylaxis is achieved with 480–960 mg Cotrimoxazole if the CD4 is less than 200 cells/ $\mu$ L, and secondary prophylaxis using lower doses of the treatment regimen should continue until immune reconstitution.

Prevention of *Toxoplasma gondii* ingestion through contamination with cat feces, undercooked red meat, and soil should be advised.

### CRYPTOSPORIDIOSIS (TABLE 117.14)

*Cryptosporidium species* may cause diarrhea and abdominal cramps in immunocompetent as well as immunosuppressed hosts; however, in those with a CD4 count of less than 100 cells/ $\mu$ L, the symptoms may be particularly severe and progress to chronicity. Prior to the advent of ART, it was the commonest pathogen identified in an HIV positive individual with diarrhea.

The mainstay of treatment is supportive with fluid and electrolyte replacement if necessary, and symptomatic treatment of diarrhea. Many antibacterial agents have been used, but with limited success, and the only consistently successful intervention is immune restoration through the initiation of ART.

**Table 117.14:** Recommendations for the Management of Cryptosporidiosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Initiate or optimize HAART for effective immune reconstitution Symptomatic treatment of diarrhea Oral or intravenous fluid and electrolyte replacement <b>Alternative:</b> Trial of nitazoxanide 500–1000 mg PO 2 × daily for 2 weeks in addition to measures listed above	<b>Preferred:</b> ART Maintenance of fluid and electrolyte balance Constipating agents such as loperamide 4 mg initially, then 2 mg with each unformed stool to a maximum of 16 mg daily	<b>Preferred:</b> ART Oral or intravenous rehydration Paromomycin 500 mg PO 4 × daily for 2–3 weeks Or Nitazoxanide 500 mg bid PO Or Azithromycin 500 mg PO daily for 5 days <b>Anti-diarrheal agents:</b> Codeine phosphate 30–60 mg 3 × daily or loperamide 2–4 mg 3 or 4 × daily to maximum of 32 mg in 24 hours

Boiling potentially contaminated drinking water for one minute may reduce the ingestion of viable oocysts.

Symptoms often resolve when CD4 greater than 100 cells/ $\mu$ L.

**Table 117.15:** Recommendations for the Management of Microsporidiasis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Initiate or optimize HAART for effective immune reconstitution For gastrointestinal infection caused by <i>E. bienuesi</i> : Fumagillin 20 mg PO 3 × daily  <b>For non-ocular infection not caused by <i>E. bienuesi</i> or <i>V. corneae</i>:</b> Albendazole 400 mg PO 2 × daily until CD4 >200 cells/μL  <b>For ocular infection:</b> Topical fumagillin 3 mg/ml eye drops. 2 drops every 2 hours for 4 days, then 2 drops daily PLUS albendazole 400 mg PO 2 × daily	No recommendation	<b>Preferred:</b> If disseminated disease: Itraconazole 400 mg PO OD plus Albendazole 400 mg PO 2 × daily

**MICROSPORIDIASIS (TABLE 117.15)**

Microsporidia are a group of related organisms, the commonest species implicated in HIV-related diarrhea are *Enterocytozoon bienusi* and *E. intestinalis*. Ophthalmic infection may occur with some species (e.g., *Vittaforma corneae*), and manifests as a keratitis.

Fumagillin has been shown to be effective for infections caused by *E. bienusi*, and albendazole with infections caused by *E. intestinalis*. If Fumagillin is used, then a response should be anticipated by 4 weeks of therapy. However, symptoms often resolve with an ART-induced increase in CD4 count to greater than 100 cells/μL.

**ISOSPORIASIS (TABLE 117.16)**

Although the typical manifestation of *Isospora belli* infection is 2–3 weeks of self-resolving small bowel diarrhea, it may

**Table 117.16:** Recommendations for the Management of Isosporiasis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Trimethoprim-sulfamethoxazole 160/800 mg PO 2–4 × daily for 7–10 days or longer if symptoms persist  <b>Alternative:</b> Pyrimethamine 50–75 mg PO daily plus leucovorin 10–25 mg PO daily Or Ciprofloxacin 500 mg PO 2 × daily for 7 days	<b>Preferred:</b> Trimethoprim-sulfamethoxazole 160/800 mg PO 4 × daily for 7 days	<b>Preferred:</b> Trimethoprim-sulfamethoxazole 320/1600 mg 2 × daily or 160/800 mg 4 × daily for 10 days followed by 160/800 mg 3 × daily for 3 weeks  <b>Alternative:</b> Pyrimethamine and folinic acid for 1 month (no dose recommendations)

Rehydration may be necessary.

cause chronic diarrhea and occasionally biliary disease in the immunocompromised. It is predominantly found in the tropics. Relapse is common therefore secondary prophylaxis should be maintained until the CD4 count is greater than 200 cell/μL. Symptoms should improve within 2–3 days of effective therapy.

**Bacterial Opportunistic Infections****MYCOBACTERIUM TUBERCULOSIS (TABLE 117.17)**

Latent *Mycobacterium tuberculosis* infection (TB) reactivation is 80–100 times more common in HIV infected patients, and in endemic areas primary TB is also common. The clinical presentation may differ depending on the CD4 count, but treatment regimens, duration and outcomes are similar to those of HIV negative TB infected patients. The management of TB/HIV coinfection is complex, and reference to local or international guidelines is recommended. Websites for relevant TB treatment guidelines are listed below. The timing of ART in HIV positive individuals is currently controversial. If a patient develops TB whilst taking ART then the ART should be continued, with dose adjustment for drug interactions where necessary. If TB and HIV are diagnosed simultaneously, then TB treatment should be initiated first. The urgency of ART initiation may depend on the CD4 count and risk of HIV disease progression. Current evidence suggests a potential benefit from early rather than delayed ART across most CD4 spectra.<sup>5</sup> The common manifestations of IRIS may cause worsening of symptoms, but overall mortality and morbidity may be improved.

**MYCOBACTERIUM AVIUM COMPLEX (MAC) (TABLE 117.18)**

*Mycobacterium avium* complex is a common cause of fevers, anemia, weight loss, and raised alkaline phosphatase, especially prior to the advent of ART and primary prophylaxis. It appears to be less common in areas where *M. tuberculosis* is endemic.<sup>7</sup> Treatment duration may be required for up to 12 months, and at least until the CD4 count is reliably greater than 100 cells/μL. Response to treatment should occur within 2–4 weeks, and treatment failure is defined by positive blood cultures 4–8 weeks into treatment. ART should be commenced within the first few weeks of treatment, as clearance without immune reconstitution is unlikely. IRIS is common with the initiation of ART, but can be differentiated from treatment failure by the absence of viable micro-organisms. Non-steroidal anti-inflammatory drugs may be useful in symptom control. Primary prophylaxis with azithromycin 1.2 g weekly should be considered in those with a CD4 count less than 50 cells/μL.

**BACILLARY ANGIOMATOSIS (TABLE 117.19)**

The causative organisms of bacillary angiomatosis are *Bartonella henselae* and *B. quintana*. In addition to skin lesions these bacteria may cause fevers, anemia, bony lesions, and peliosis hepatis. Microbiological response to antibiotics is rapid, but clinical

**Table 117.17:** Recommendations for the Management of Mycobacterium Tuberculosis Infection

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<p><b>Preferred:</b> Refer to CDC TB guidelines available at <a href="http://www.cdc.gov/tb/">www.cdc.gov/tb/</a></p> <p><b>Doses:</b> Weight and dose-frequency dependent—see specific guideline</p> <p><b>Preferred:</b> Initiation 2 months RHEZ (rifabutin can be substitute for rifampicin). Ethambutol can be discontinued if drug resistance testing shows organism sensitive to RHZ. Continuation with RH to complete 6 months of treatment for pulmonary TB, (extend to 9 months if still culture positive at 2 months of therapy or severe extrapulmonary TB) If CNS/bone or joint involvement extend to 9–12 months. A selection of alternative regimens are available if evidence of rifamycin/isoniazid or multi/extensively drug-resistant organism is cultured. See specific guideline.</p>	<p><b>Preferred:</b> Refer to national guidelines</p> <p><b>Alternative:</b> Use WHO treatment recommendations listed below: Latest version available at : <a href="http://www.who.int/tb/en/">www.who.int/tb/en/</a> Directly observed therapy daily recommended, especially in the induction phase, or when R used.</p> <p><b>Doses:</b> Isoniazid 5 mg/kg daily or 10 mg/kg 3 × weekly Rifampicin 10 mg/kg daily or 10 mg/kg 3 × weekly Pyrazinamide 25 mg/kg daily or 25 mg/kg 3 × weekly Streptomycin 15 mg/kg daily or 15 mg/kg 3 × weekly Ethambutol 15 mg/kg daily or 30 mg/kg 3 × weekly</p> <p><b>Regimens:</b> New TB in HIV positive: 2 months HRZE followed by 4 months HR or 6 months HE. If HE used (not preferred option), must be given daily. If sterile facilities permit, E may be replaced with S in induction phase. Advised in cases of meningeal TB. Previously treated smear positive TB: 2 months HRZES followed by 1 month HRZE followed by 5 months HRE Chronic or multidrug-resistant TB—consult specialist for individualized regimen.</p>	<p><b>Preferred:</b> Refer to Revised National TB Control Programme guidelines available at <a href="http://www.tbcindia.org/">www.tbcindia.org/</a></p> <p><b>Doses:</b> Isoniazid 600 mg 3 × weekly Rifampicin 450 mg (600 mg if weight &gt;60 kg) 3 × weekly Pyrazinamide 1500 mg 3 × weekly Ethambutol 1200 mg 3 × weekly Streptomycin 0.75 g 3 × weekly (0.5 g if younger than 50 years).</p> <p><b>Preferred: All directly observed</b> New TB in HIV positive 2 months HRZE 3 × weekly followed by 4 months HR 3 × weekly</p> <p><b>Previously treated TB:</b> 2 months HRZES then 1 month HRZE then 5 months HRE, all 3 × weekly If tuberculous meningitis, miliary TB, bone or joint involvement, continuation phase should continue to complete 12 months of therapy</p>

Abbreviations: R, rifampicin; H, isoniazid; E, ethambutol; Z, pyrazinamide; S, streptomycin.

Continuation phase of HR rather than H is preferred.

Although CDC 2003 guidelines permit intermittent therapy twice weekly this is not recommended in HIV positive individuals in other guidelines due to concerns of treatment failure.

Multiple drug interaction with HIV medications which may require dose adjustment of rifamycin component of TB treatment, and antiretrovirals:

See [www.HIV-druginteractions.org](http://www.HIV-druginteractions.org) for more details.<sup>6</sup>

Rifabutin instead of rifampicin should be used if in combination with boosted protease inhibitor.

Patients receiving isoniazid should receive pyridoxine 25–50 mg PO daily to reduce risk of peripheral neuropathy.

CDC guidelines recommend 6–8 weeks of corticosteroid for CNS disease.

TB is a common cause of paradoxical reaction and immune reconstitution inflammatory disease.

**Table 117.18:** Recommendations for the Management of MAC Infection

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<p><b>Preferred:</b> Clarithromycin 500 mg PO 2 × daily plus ethambutol 15/mg/kg daily Consider addition of rifabutin 300 mg PO daily (caution-drug interactions with HAART)</p> <p><b>Alternative:</b> Azithromycin 500–600 mg daily plus ethambutol 15/mg/kg daily</p> <p><b>Alternative 3rd and 4th agents include:</b> Amikacin 10–15 mg/kg IV daily Streptomycin 1 g IV/IM daily Ciprofloxacin 500–750 mg PO 2 × daily Levofloxacin 500 mg PO daily Moxifloxacin 400 mg PO daily</p>	<p>Azithromycin 500–600 mg daily, or Clarithromycin 500 mg 2 × daily plus ethambutol 15/mg/kg/daily plus rifabutin 300 mg daily If no MAC therapy available, start ART.</p>	<p>Clarithromycin or azithromycin with ethambutol. Consider a third agent such as rifabutin or ciprofloxacin. No dose recommendations given. MAC perceived to be uncommon in India</p>

Drug resistance testing, if available, should guide therapy.

IRIS common on initiation of ART.

More experience and quicker time to negative cultures with clarithromycin vs. Azithromycin.

Addition of 3rd agent reduces drug resistance development, and should be considered in those with CD4 < 50 or high bacterial loads.

**Table 117.19:** Recommendations for the Management of Bacillary Angiomatosis

CDC-USA <sup>1</sup>	WHO (SE Asia) <sup>2</sup>	NACO-India <sup>3</sup>
<b>Preferred:</b> Erythromycin 500 mg PO or IV 4 × daily for 3 months Or Doxycycline 100 mg PO or IV 2 × daily for 3 months <b>If CNS or severe infection:</b> Doxycycline 100 mg PO or IV 2 × daily +/- Rifampicin 300 mg PO or IV twice daily for 4 months <b>Alternative:</b> Azithromycin 500 mg daily or Clarithromycin 500 mg 2 × daily	<b>Preferred:</b> Erythromycin 500 mg PO 4 × daily <b>Alternative:</b> Doxycycline 100mg 2 × daily Consider addition of rifampicin 300 mg 2 × daily PO if severe disease or immunosuppressed	<b>Preferred:</b> Erythromycin 500 mg PO 4 × daily or doxycycline 100 mg PO or IV for at least 3 months <b>Alternative:</b> Azithromycin 600 mg daily

Jarisch–Herxheimer reaction to treatment may occur within the first 48 hours of treatment.

Pretreatment with an antipyretic may attenuate this reaction.

response is more gradual, with frequent relapses unless immune reconstitution is achieved. Severely immunocompromised individuals should avoid fleas and lice where possible.
